Background: It is widely accepted that neurogenesis in humans ends around the middle of gestation. However, the subventricular zone of some focal telencephalic domains continues with neuron production throughout the last trimester. **Aims**: The aim of our study was to determine if late neurogenesis might also occur in the major proliferative zones of the telencephalon. **Methods:** We evaluated Nissl, Golgi and immunohistochemically stained human slides from the Zagreb Neuroembryological Collection. **Results**: Between 24-26 postconceptional weeks (pcw) a massive stream of densely packed cells was found leaving the ganglionic eminence (GE), a progenitor domain of the ventral telencephalon that is a major source of cortical GABAergic neurons. Between 32-36 pcw, the GE decreased in size but was clearly distinguishable, and a stream of non-radially oriented MAP-2 positive migratory-like cells still extended towards the dorsal telencephalon. Additionally, volumetric analysis on MRI images was performed to evaluate the developmental pattern of the GE in period from 13 to 34 pcw and found a persistent GE throughout the entire analyzed period. This suggests that the GE maintains its proliferative capabilities up to the end of gestation and that a significant production of cortical GABAergic neurons continues beyond the proliferative period of principal glutamatergic neurons. **Conclusion:** We propose that protracted neurogenesis from the GE contributes to the disproportional increase in the number of calretinin neurons, the most numerous GABAergic neuron population in primates. We further suggest that late fetal production of neurons is not restricted to neurons within the dentate gyrus and rostral migratory stream.

Linking integrity of visual pathways trajectories to visual behavior deficit in very preterm infants.
Low-risk premature infants often develop visual deficits, even in the absence of ophthalmological complications and high-graded brain injury. These complications can be explained by the nature of subtle perinatal lesions and alterations of brain growth due to the prematurity. Subtle brain injuries and vulnerability of axonal pathways can be observed in spatiotemporal context of the white matter segments. The aim of this study was to examine the link between MRI quantitative (brain metrics data) and qualitative features (visibility of 2nd white matter segment - sagittal strata and periventricular crossroads C1-C6) and visual behavior in preterm neonates at term-equivalent age. Seventy-one very preterm infants without high-graded brain injury on MRI and no ocular pathologies were studies. The infants received MRI scans at term-equivalent age. MRI scans were analyzed using (a) simple brain metrics and (b) scoring the visibility of transient structural patterns (sagittal strata and periventricular crossroads). At the median age of 41 PMA weeks infants completed the Neonatal Visual Assessment. Results indicated that visibility of temporal crossroad area C6 and frontal and occipital sagittal strata was positively correlated with visual tracking skills in neonatal period. Furthermore, the visibility of frontal and occipital sagittal strata were strong predictors of total Neonatal Visual Assessment score. The findings confirmed that sagittal strata and periventricular crossroads prominence is a valuable additional marker in perinatal neuroimaging at term-equivalent age. Thus, alteration in MRI appearance of temporal crossroad and sagittal strata may be useful in predicting of visual behavior for very premature born infants.

A NOVEL FUNCTION FOR MIRK/DYRK1B KINASE IN THE COLUMNAR ORGANIZATION OF MEDIAL LATERAL MOTOR NEURONS IN THE EMBRYONIC CHICK SPINAL CORD

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Nikolaos Kokkorakis[1], Panagiotis Politis[2], Rebecca Matsas[1], Maria Gaitanou[1]
[1]Hellenic Pasteur Institute, Laboratory Of Cellular And Molecular Neurobiology-stem Cells, Athens, Greece, [2]Biomedical Research Foundation of the Academy of Athens, Center Of Basic Research, Athens, Greece

Aims: Dyrk1B is a dual-specificity kinase involved in growth arrest and differentiation, playing a major role in cancer progression. Our aim is to elucidate the role of Dyrk1B in spinal cord development. **Methods**: *Gain-and-loss-of-function and mechanistic rescue phenotype experiments* were performed in E2 chick neural tube by unilateral *in ovo* electroporation of Dyrk1B/GFP and GFP constructs, administration of AZ191 inhibitor or both of them together respectively. **Results**: Forced expression of Dyrk1B in E2 chick neural tube resulted in increased cell cycle exit and apoptosis at E4, while neuronal differentiation is slightly induced. The observed increased apoptosis in VZ and motor neuron (MN) domain combined to premature cell cycle exit resulted in the reduction of motor neuron progenitors (pMNs), as well as of post-mitotic motor neurons (MNs). This intense ventral phenotype of Dyrk1B function indicates the possible involvement of SHH signaling. In agreement, the real-time qPCR analysis revealed that Dyrk1B overexpression reduces dramatically SHH and Gli3 mRNA levels. At E6, the fewer MNs resulted in the formation of a reduced medial LMC region (LMCm), while no changes were observed at the lateral LMC region (LMCl), or in the medial motor column (MMC). AZ191 administration at E2 showed the opposite phenotype, resulting in increased proliferation at E4, while mechanistic rescue phenotype experiments, applying AZ191 1h after Dyrk1B/GFP electroporation, confirmed the inhibitor specificity. **Conclusions**: We revealed a novel role for Mirk/Dyrk1B kinase in spinal cord development. Dyrk1B overexpression alters the columnar organization of LMCm MNs. The mechanism of Dyrk1B function is under investigation.

Minibrain-related kinase/dual-specificity tyrosine-regulated kinase 1B implication in stem/cancer stem cells biology.
Dual-specificity tyrosine phosphorylation-regulated kinase 1B (DYRK1B), also known as minibrain-related kinase (MIRK) is one of the best functionally studied members of the DYRK kinase family. DYRKs comprise a family of protein kinases that are emerging modulators of signal transduction pathways, cell proliferation and differentiation, survival, and cell motility. DYRKs were found to participate in several signaling pathways critical for development and cell homeostasis. In this review, we focus on the DYRK1B protein kinase from a functional point of view concerning the signaling pathways through which DYRK1B exerts its cell type-dependent function in a positive or negative manner, in development and human diseases. In particular, we focus on the physiological role of DYRK1B in behavior of stem cells in myogenesis, adipogenesis, spermatogenesis and neurogenesis, as well as in its pathological implication in cancer and metabolic syndrome. Thus, understanding of the molecular mechanisms that regulate signaling pathways is of high importance. Recent studies have identified a close regulatory connection between DYRK1B and the hedgehog (HH) signaling pathway. Here, we aim to bring together what is known about the functional integration and cross-talk between DYRK1B and several signaling pathways, such as HH, RAS and PI3K/mTOR/AKT, as well as how this might affect cellular and molecular processes in development, physiology, and pathology. Thus, this review summarizes the major known functions of DYRK1B kinase, as well as the mechanisms by which DYRK1B exerts its functions in development and human diseases focusing on the homeostasis of stem and cancer stem cells.

The subthalamic nucleus (STN) is an important node in the basal ganglia circuitry. The developmental origin and molecular markers of STN have been adequately studied in animal models. However, there is a need to elucidate the molecular markers guiding the development of the human STN, as this nucleus is involved in the motor, associative, and limbic functions of the cortico-basal ganglia-thalamocortical circuitry. Moreover, some transcription factors identified in the STN of experimental animals are implicated in several neurodevelopmental disorders, but the structural and molecular changes of STN's neuronal population in these disorders were never thoroughly explored. **Aims** The aim of the study was to identify spatio-temporal expression patterns of transcription factors relevant for the differentiation and specification of STN's neuronal population. **Methods** This study encompassed postmortem, formalin-fixed, paraffin-embedded human fetal brain tissue from the early fetal period (12-15 post-conceptional weeks, PCW) to term. Indirect immunohistochemistry with antibodies for transcription factors FOXA1, FOXP1, FOXP2, BARHL1, and PAX6 was performed on 10µm thin sections. **Results** We show that the developing human STN expresses transcription factors previously shown to be involved in the development of rodent STN. Moreover, the human STN expresses some transcription factors that were not previously described in animal models. **Conclusions** Our preliminary study accentuates the need to study the transcription factors in the developing human STN because the results from animal models cannot fully predict the human STN's molecular markers. Elucidating the STN's transcriptional profile could advance our understanding of its functional properties and its role in neurodevelopmental disorders.

Aims: The nervous system is a complex network of distinct cell types organized in a highly stereotypical pattern, each with unique morphology, projection and function. A fundamental goal in neuroscience is deciphering the diversity and heterogeneity of neuronal cells in organization of neural circuits. Neurons are generated through multiple divisions of stem cells. In *Drosophila*, neural progenitors use two axes of information, spatial and temporal, to generate the cellular diversity of the central nervous system. The neuroblasts at the tip of OPC (outer proliferation center) epithelium transit through the series of tTFs as they age and the combinatorial input of spatial and temporal factors allows the generation of different neuronal types. **Methods:** A laser-based flow cytometry, fluorescence-activated cell sorting (FACS Aria III), 10X Genomics single cell technology and NovaSeq 6000 sequencing platform are used to determine the complete gene-expression profile of individual neuroblasts and neurons during development. **Results:** By combining single cell mRNA sequencing with computational methods, we identified the whole series of temporal TFs that specify optic lobe neurons that arise from tOPC region. We also identified complete set of neurons coming from different temporal windows within this region. **Conclusion:** Our results show how the single cell mRNA sequencing can be used to characterize regulation of temporal transcription factors and the way the different set of neurons are generated.

miR-128 is a highly abundant, brain-enriched miRNA with important functions in the regulation of migration, dendritic outgrowth and excitability of upper layer (UL) neurons in the mouse cerebral cortex. In vertebrates, miR-128 is located within introns of R3H-domain family RNA binding proteins (RBPs). This arrangement allows miR-128 activity to be leveraged at a second posttranscriptional level: the co-regulation of a subset of miR-128 mRNA targets by the miR-128-2 host gene product, a poly(U)-specific RBP. Surprisingly, ARPP21 target RNAs were specifically enriched for miR-128 binding sites, suggesting that ARPP21 directly antagonizes miR-128 activity on an overlapping set of mRNAs. In contrast to miR-128, we have shown that ARPP21 acts as a positive post-transcriptional regulator, at least in part through interaction with the translation initiation complex. Proximity ligation assays suggest that ARPP21 functionally interacts with multiple 5'-Cap and poly(A) binding complexes. We have shown that miR-128 overexpression inhibits migration to the UL and impairs dendritic arborization. We now show that CRISPR-mediated miR-128 knockdown leads to aberrant apical dendrite orientation and geometry. Persistent expression of miR-128 in radial glia leads to reduced generation and impaired cortical astrogenesis. Manipulation of the two miR-128 host genes, ARPP21 or R3HDM1, oppose the action of miR-128 on UL neuron migration and dendritogenesis by promoting migration and enhancing arbor complexity. We believe these antagonistic functions provide a tunable post-transcriptional switch with relevance for intellectual disability linked to mutations in R3HDM1 and miR-128 target genes.

Heme is an iron-containing porphyrin of vital importance that orchestrates cellular metabolism. Indeed, heme regulates the TCA cycle flux, the activity of the electron transport chain (ETC) complexes, ATP synthesis, and thermogenesis. Proper regulation of energetic metabolism is crucial during neurogenesis and metabolic dysfunctions often result in neurodevelopmental defects. Interestingly, recent data associate defective heme import in the developing brain with microcephaly and hydrocephalus in both humans and mice. Curiously, the heme exporter FLVCR1 is highly expressed in the embryonic nervous tissues and zebrafish lacking FLVCR1 showed hydrocephalus.
To better dissect the role of heme trafficking in the regulation of neurodevelopment, heme levels were genetically manipulated in neuronal progenitors in mice by targeting the plasma membrane heme exporter FLVCR1a.
Mice lacking Flvcr1a in neuronal progenitors (Flvcr1afl/fl; Nes-Cre mice) die perinatally due to severe neurodevelopmental defects: E18,5 Flvcr1afl/fl; Nes-Cre embryos showed microcephaly and hydrocephalus. Analysis of E14,5 Flvcr1afl/fl; NesCre embryos cortex showed increased apoptosis; however, no differences in cell proliferation were detected at this stage. Moreover, a decrease in neural progenitors, as well as a decreased number of differentiating neural cells, were observed in Flvcr1afl/fl; NesCre developing brains compared to controls.
Finally, metabolic analyses showed that the brain of E14,5 Flvcr1afl/fl; NesCre embryos were characterized by decreased activity of enzymes involved in glycolysis, ETC, reduced mitochondrial ATP levels, and increased lipid peroxidation compared to controls.
Together these data reveal an essential role of FLVCR1 during neurodevelopment and suggest that its action is mediated by the fine regulation of energetic metabolism.

Over recent years, compelling evidence has outlined that developmental trajectories are altered in a genetic rare condition, the Niemann Pick C1 (NPC1) disease. NPC1-deficiency is characterized by late endosomal accumulation of unesterified cholesterol, which leads to impaired cholesterol homeostasis and a broad range of cellular abnormalities, including alterations in mitochondrial electron transport chain and increased oxidative stress (OS).
To investigate the possibility that OS affects the complex sequence of events leading to neuronal maturation, we have established two *in vitro* cell models, using *Npc1* KO mid-gestation embryos as donors: i) neural precursor cells (NSCs), which rapidly grow and form neurospheres *in vitro* when maintained under stemness conditions; and, ii) mouse embryonic fibroblasts (MEFs), which can be easily expanded, obtaining large cell amounts required for biochemical approaches. The NSC self-renewal potential, determined by measuring neurosphere diameter, resulted significantly reduced in neurospheres of *Npc1* KO compared to *wt* ones. Consistently, the expression of Pax6 and Sox2, typical markers of stemness maintenance, was already reduced at DIV1, whereas the expression of differentiation markers, such as beta3-tubulin concomitantly increased. This finding indicates that Npc1-deficiency determines a reduction of NSC proliferation ability, anticipating their switch to differentiation. Of note, differentiating *Npc1* KO neurons, displayed longer neurites and a higher level of neurite sprouting, *i.e*. increased neurite number and branching, when compared to *wt* neurons. Redox signaling mechanisms involved in the regulation of neuronal development were studied in MEFs, observing that the transcriptional activation of antioxidant genes was disturbed in *Npc1* KO MEFs.

AGO-APP FOR IDENTIFIYING A NEUROGENESIS REGULATING MICRO-RNA NETWORK IN FLY

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Christophe Beclin[1], Andrea Erni[2]
[1]CNRS, Ibdm, marseille cedex , France, [2]cnrs, Ibdm, marseille cedex, France

MicroRNAs are small regulatory molecules that negatively control mRNA translation. The microRNA pathway is required for most, if not all, of the developmental processes that have been studied so far. However, many aspects regarding the exact mode of action of microRNAs are still unclear. To decipher the precise role of microRNAs during neurogenesis, we have developed a new in vivo tool called Ago-APP. Ago-APP is based on the controlled expression of a small T6B peptide allowing immuno-precipitation and sequencing of micro-RNAs. We have generated three Drosophila lines where T6B expression can be specifically induced in neuroblasts, neurons or glial cells, respectively. From these lines we have identified sets of micro-RNAs specifically active in one of the 3 cell types. The cell-type specific activity of some of these microRNAs has been verified using reporter fly lines. We have initiated the functional analysis of neuroblast microRNAs. Using overexpression approaches, we confirmed the ability of neuroblast microRNAs to target neurogenic transcription factors and control neurogenesis. However, loss-of-function experiments generally induced no or very few differentiation defects suggesting that microRNAs naturally act synergistically to regulate neurogenesis. To confirm this hypothesis, we generated Drosophila lines harboring sponge constructs designed to simultaneously downregulate more than one microRNA (from 2 to 8). Analysis of these Drosophila lineages, including the ability of neuroblasts to maintain an immature state when sponges are expressed, is ongoing.

GESTATIONAL EXPOSURE TO FUNGICIDE RESIDUES CORRUPTS NEUROGENESIS AND SYNAPTIC FUNCTIONS

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Anaïs Vignon[1], Yunyun Wang[2], Pierre-André Lafon[2], Lucie Salvador-Prince[1], Joan Torrent[1], Véronique Perrier[1]
[1]Institute of Neurosciences Montpellier, Neurosciences, Montpellier, France, [2]Huazhong University of Science and Technology, Cellular Signalling Laboratory, WUHAN, China

Neurogenesis plays a crucial role during neurodevelopment and its dysfunction can lead to neurodevelopmental disorders. The presence of pesticide residues in the environment represents a threat of which we have recently become aware of. Contaminants could corrupt neurogenesis during gestation, potentially leading to impaired neuronal and synaptic functions. Since the effects of this low-noise contamination have not yet been evaluated on neurodevelopment, we investigated the impact of fungicide residues on WT mice exposed throughout gestation. Mice were exposed to fungicides, cyprodinil, mepanipyrim and pyrimethanil, alone or in cocktail in the drinking water at 0.1 µg/L from gestation to weaning. The dose selected in the drinking water corresponds to the regulatory limit dose allowed by EU. Results showed that gestational exposure to fungicide residues substantially promoted an increase of neural precursor cells at P3. This corrupted neurogenesis was linked to increased levels of β-catenin, through the crosstalk of the PI3K/Akt and Wnt/β-catenin pathways, both involved in cell proliferation. Fungicide exposure also altered protein expression of PSD95 and NMDA receptors in P3 neonates, two targets of the β-catenin signaling pathway. The alteration of the expression of these synaptic proteins leads to synaptic transmission dysfunctions at P18. Exposed-mice are unable to elicit an hippocampal long term depression, which is a key mechanism in memory. Corruption of neurogenesis and synaptic functions by these fungicide residues could be a fertile ground for the development of neurodevelopmental disorders as autism spectrum disorders or other diseases associated with memory deficits.

Deconstructing Alzheimer's Disease: How to Bridge the Gap between Experimental Models and the Human Pathology? Discovered more than a century ago, Alzheimer's disease (AD) is not only still present in our societies but has also become the most common dementia, with 50 million people worldwide affected by the disease. This number is expected to double in the next generation, and no cure is currently available to slow down or stop the disease progression. Recently, some advances were made due to the approval of the aducanumab treatment by the American Food and Drug Administration. The etiology of this human-specific disease remains poorly understood, and the mechanisms of its development have not been completely clarified. Several hypotheses concerning the molecular mechanisms of AD have been proposed, but the existing studies focus primarily on the two main markers of the disease: the amyloid β peptides, whose aggregation in the brain generates amyloid plaques, and the abnormally phosphorylated tau proteins, which are responsible for neurofibrillary tangles. These protein aggregates induce neuroinflammation and neurodegeneration, which, in turn, lead to cognitive and behavioral deficits. The challenge is, therefore, to create models that best reproduce this pathology. This review aims at gathering the different existing AD models developed in vitro, in cellulo, and in vivo. Many models have already been set up, but it is necessary to identify the most relevant ones for our investigations. The purpose of the review is to help researchers to identify the most pertinent disease models, from the most often used to the most recently generated and from simple to complex, explaining their specificities and giving concrete examples.

Introduction: Brain injuries activate neural stem cells in the subventricular zone (SVZ) to produce a higher number of neuroblasts. But neuronal replacement is very limited and does not result in functional recovery. **Aim:** The aim of this work is to see if the treatment with EOF2 is capable of achieving the maturation and integration of these new neuroblasts in the injured region. **Methods:** We have analyzed the effect of the EOF2, that facilitates the release of neuregulin 1 and stimulates neuroblast differentiation, on the generation of new neurons in response to a mechanical cortical brain injury. Using GFP-expressing lentiviral vectors, we have labelled cells of the SVZ before performing mechanical injuries in the primary motor cortex of mice. We have studied the migration towards the injury and have analyzed the functional properties of these cells over the course of 14 to 56 days post injury (dpi). **Results:** Not treated mice show very little or no GFP-labelled cells in the perilesional area. 14 dpi GFP-labelled cells did not show active membrane properties. 28 dpi depolarized resting membrane potentials were observed and 5% of the recorded cells showed action potentials. At this time some recorded cells showed synaptic inputs, which suggest they have integrated into existing circuits. 56 dpi the GFP-labelled neurons showed resting membrane potentials and action potentials values similar to those of mature neurons. **Conclusion:** We conclude that treatment with EOF2 promotes migration of newly generated neuroblasts towards the injury that functionally differentiate into mature neurons.

The ependymal cells are specialized cells lining the surface of the brain ventricles and spinal canal. They carry bundles of motile cilia on their apical surface, which beat and contribute to directional CSF flow. They typically originate from radial glia cells and are highly conserved among vertebrates Defects in these cells can lead to a variety of neurological conditions, affecting brain function. Despite this, ependymal cells remain largely understudied. We use zebrafish as a model to characterize ependymal cells and better understand their function in brain development and physiology. In the larval zebrafish brain these cells appear early in development and display a single cilium while multiciliated cells (MCCs) carrying multiple cilia are born later in development. It however remains unclear when and where these MCCs are established and how they contribute to brain function. In our study, we identified two different lineages of motile ciliated cells and showed that these lineages are heterogenous in their expression of *Foxj1* family of ciliary master regulators. Our study also depicts that during development there is a transition from mono- to multiciliated cells (MCCs) driven by *gmnc*. Finally, we revealed the role of these ependymal cells in morphogenesis of the brain by contributing to ventricular development. In conclusion our research depicts that in the zebrafish ependymal cells have a remarkable degree of similarity as well as some differences with mammals.

Diversity and function of motile ciliated cell types within ependymal lineages of the zebrafish brain.
Motile cilia defects impair cerebrospinal fluid (CSF) flow and can cause brain and spine disorders. The development of ciliated cells, their impact on CSF flow, and their function in brain and axial morphogenesis are not fully understood. We have characterized motile ciliated cells within the zebrafish brain ventricles. We show that the ventricles undergo restructuring through development, involving a transition from mono- to multiciliated cells (MCCs) driven by gmnc. MCCs co-exist with monociliated cells and generate directional flow patterns. These ciliated cells have different developmental origins and are genetically heterogenous with respect to expression of the Foxj1 family of ciliary master regulators. Finally, we show that cilia loss from the tela choroida and choroid plexus or global perturbation of multiciliation does not affect overall brain or spine morphogenesis but results in enlarged ventricles. Our findings establish that motile ciliated cells are generated by complementary and sequential transcriptional programs to support ventricular development.

ROLE IN NEURAL STEM CELL DIFFERENTIATION OF CHD8 AND CHD7, CHROMATIN REMODELERS, IMPLICATED IN AUTISM SPECTRUM DISORDER

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Corentine Marie[1], Morgane Pigache[1], Jean-Baptiste Hure[1], Haikun Liu[2], Bassem Hassan[1], Carlos Parras[1]
[1]Institut du Cerveau, Brain Development Team, Paris, France, [2]DKFZ-ZMBH Alliance, Division Of Molecular Neurogenetics, Heidelberg, Germany

Autism spectrum disorder (ASD) affects approximately 1 in 70 people. Most ASD risk genes are expressed during brain development having roles either in neuronal communication or in regulation of gene expression, with CHD8 chromatin remodeler being the most frequently mutated gene in ASD patients. We previously showed that specific deletion of *Chd8* in oligodendroglia leads to strong defects in oligodendrocyte development and myelination. In addition, mutations in its paralog CHD7 are the cause of CHARGE syndrome, which also presents autistic phenotypes, and we previously showed that *Chd7* specific deletion in oligodendroglia impairs normal oligodendrocyte differentiation and myelination in mouse models and children with *CHD7* mutations. In this study, we aimed to understand the role of these chromatin remodelers in NSC differentiation into different neural subtypes, neurons, astrocytes and oligodendroglia. Using postnatal electroporation to label neural stem cells (NSCs) from neonatal subventricular zone and trace their progeny, we present evidences for an essential role of Chd7 and Chd8 chromatin remodelers in brain NSC differentiation. First, we show that Chd7 and Chd8 bind together to regulatory regions of genes involved in oligodendrogenesis, neurogenesis, and astrogenesis, suggesting they regulate all these biological processes. Second, double knockout NSCs, present a decrease in the total number of cells they generate, with oligodendroglia being the most decreased cell-lineage, followed by a strong reduction in olfactory bulb neurons, and a smaller reduction in astrocytes. We believe that further understanding of Chd7 and Chd8 implication in the NSC differentiation should help to develop therapeutic treatments for ASD patients.

Einstein College of Medicine, Yeshiva University, Neuroscience Department, New York, Italy, [4]National Research Council of Italy, Institute For The Organic Synthesis And Photoreactivity, Bologna, Italy

The glial water channel AQP4 has emerged as an important player regulating neurogenesis in healthy and diseased brain. AQP4 forms ordered structures named Orthogonal Arrays of particles (OAPs) whose size depends on the ratio of its major isoforms, M1 and M23. Consistent with the relevance of controlling cell volume changes during neural development, AQP4 is markedly expressed in Neural Stem Cells (NSCs). AQP4 deletion is known to inhibit proliferation, migration, and neuronal differentiation of NSCs cultured *in vitro* but does not impact glial differentiation. The aim of this study is to investigate the selective role of the OAP-forming M23-AQP4 isoform in regulating NSC differentiation. E14 embryonic NSCs were prepared from WT, OAP-null mice lacking M1-AQP4 isoform and AQP4 knockout (KO) mice. Floating neurospheres were allowed to differentiate for 3, 7, 14 and 21 days and analyzed by immunofluorescence, immunoblotting and functional assays. WT and OAP-null NSCs revealed a progressive decrease in the NSC marker Nestin and time-related increase in GFAP and AQP4, whose level reflected in the upregulated water transport rate. We found that the lack of AQP4 significantly impaired both NSC proliferation and radial migration out of the neurospheres. Interestingly, compared to WT and AQP4 KO, OAP-null NSCs displayed higher viability and faster mobility as well as they failed to migrate in chains. These findings suggest that AQP4 aggregation state may be involved in the mechanobiology of astrocytes during brain development and provide useful information for stem cell technology.

THE ORGANIZATION OF THE INFERIOR OLIVE IS ALTERED IN TSHZ3 MUTANT MICE

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Xavier Caubit, Elise Arbeille, Laurent Fasano
Aix Marseille University, Ibdm Cnrs Umr 7288, Marseille, France

In mouse, newborn inferior olivary (IO) neurons derived from the neuroepithelium of the hindbrain rhombic lip. These neuronal precursors migrate tangentially in the submarginal zone from the dorsal to the ventral medulla and stop their migration before reaching the floorplate to form the immature inferior olive nucleus (ION). Near the floor plate, IO neurons first compact into a club-shaped domain, and then they organize in subnuclei that form the characteristic lamellae. The molecular mechanisms controlling the specification and the emergence of precerebral neurons as well as those controlling the migration of IO neurons towards the midline start to be elucidated, however, both the mechanism controlling the final positioning of IO neurons and the compartmentalization of the ION need more investigation. We previously showed that mice deficient for the Teashirt zinc finger homeobox 3 gene (*Tshz3*) die at birth and that *Tshz3* controls the development of diverse components of the circuitry required for breathing. Here, we analyzed the impact of *Tshz3* deletion on the development of the caudal medulla. We report that *Tshz3* inactivation specifically affects the organization of subnuclei as well as the lamellated pattern of the ION. Together our data indicate that *Tshz3* is required for the proper subdivision and final morphology of ION. We previously reported that heterozygous deletion of *TSHZ3* in 19q12 are associated with autism spectrum disorder and these new data might provide insight for understanding the pathophysiological mechanisms of this disorder.

ROLE OF THE SONIC HEDGEHOG SIGNALING PATHWAY ON THE CORTICAL DEVELOPMENT

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Justine Masson, Maria Pedraza, Valentina Grampa, Julien Puech, Christine Métin
Institut du Fer à Moulin, Umr-s 1270 Inserm/sorbonne Université, Paris, France

Sonic Hedgehog SHH is a morphogen involved in dorso-ventral patterning of brain during early development, however its role in the development of the cerebral cortex has been poorly investigated. SHH binds to its receptor Patched allowing the translocation of Smoothen in the primary cilium, a cellular compartment acting as a signaling plateform. The canonical SHH dependent pathway control gene expression through activation and repression of Gli transcription factors and depends on intraflagellar trafficking involving specific kinesins, such as KIF7. In the cortex, SHH is involved in the division/migration of principal cortical cells and in the migration of interneurons as they colonize the cortical plate. We analyzed SHH expression in the cortex between E12.5 and E16.5 and investigated the consequence of abnormal canonical SHH-dependent using *Kif7* KO on cortical development. We showed that *Shh* mRNA is expressed at low level in very few cells in the developing cortex whereas SHH protein is present throughout the proliferative and postmitotic cortical layers, suggesting significant extracortical origin for cortical SHH. Deletion of *Kif7* leads to an hyper-activated Gli dependent pathway and to gross morphological defects of the brain. We thus confirmed that the loss of *Kif7* affects cortex neurogenesis, in particular the proliferation and differentiation of principal cortical cells and the migration of cortical interneurons. Afferent and efferent cortical projections were abnormal despite normal dorso-ventral patterning of the forebrain . Our results confirmed a significant contribution of the SHH gli-dependent pathway to the cortex development, with a key role on cortical and GABAergic interneurons migration.

SEQUENTIAL NEUROGENESIS IN ZEBRAFISH HABENULA GIVE RISE TO DISTINCT FUNCTIONAL MICROCIRCUITS WITH DISTINCT COMPUTATIONAL PROPERTIES

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Francisca Acuña-Hinrichsen, Emiliano Jimenez Marquez, Anna Ostenrath, Aytac Kadir Mutlu, Emre Yaksi
Kavli Institute for Systems Neuroscience, Center For Neuronal Computation, Trondheim, Norway

Habenula is a brain region that relays forebrain activity to monoaminergic brain nuclei and was shown to play an important role in adaptive behaviors. Recently, we revealed that habenula integrates multi-sensory information with the activity of multiple ancestral cortico-limbic forebrain regions in zebrafish. We also showed that as zebrafish develop from larval to juvenile, their performance in cognitively demanding adaptive behaviors increases. These results highlight a developmental maturation and expansion of brain circuits that are required for behavioral flexibility. In line with this maturation, our recent findings showed that sequential neurogenesis in habenula give rise to ensembles of habenular neurons with different spatial locations and correlated ongoing activity. However how sequential neurogenesis in habenula contributes to formation of distinct habenular microcircuits, and how this relates to the integration of the habenula into the cortico-limbic activity and sensory inputs is yet to be discovered. By using a combination of *in vivo* birth-dating with functional brain imagining, we investigated the ongoing and sensory evoked activity of habenular neurons that are born at distinct developmental stages, together with their input regions in dorsal telencephalon. Our results revealed that habenular neurons that are born at distinct developmental time points, integrates information from distinct forebrain ensembles, and encodes sensory information differently. We also showed that distinct microcircuits of habenular neurons marked with molecular markers are populated by different waves of neurogenesis. Our results revealed that sequential neurogenesis in habenula, give rise to habenular ensembles integrating information from distinct sources encoding internal states and environmental cues.

Functional properties of habenular neurons are determined by developmental stage and sequential neurogenesis.
The developing brain undergoes drastic alterations. Here, we investigated developmental changes in the habenula, a brain region that mediates behavioral flexibility during learning, social interactions, and aversive experiences. We showed that developing habenular circuits exhibit multiple alterations that lead to an increase in the structural and functional diversity of cell types, inputs, and functional modules. As the habenula develops, it sequentially transforms into a multisensory brain region that can process visual, olfactory, mechanosensory, and aversive stimuli. Moreover, we observed that the habenular neurons display spatiotemporally structured spontaneous activity that shows prominent alterations and refinement with age. These alterations in habenular activity are accompanied by sequential neurogenesis and the integration of distinct neural clusters across development. Last, we revealed that habenular neurons with distinct functional properties are born sequentially at distinct developmental time windows. Our results highlight a strong link between the functional properties of habenular neurons and their precise birthdate.

Subcortical band heterotopia (SH) is a cerebral cortical malformation associated with epilepsy and intellectual disability. In this disorder, clusters of neurons are found localized abnormally in the white matter, below the cortex. The microtubule-associated protein Eml1/EML1 was found mutated in SH mice and patients. During corticogenesis in mutant mice, some neuronal progenitors (RG) exhibit an aberrant position, outside their ventricular proliferative zone (VZ), in the region where the heterotopia develops. RG exhibit altered primary cilia suggesting a role of Eml1 associated with this key organelle involved in cell cycle and signalling. Taking advantage of a new murine model that we generated (Eml1 cKO), we are interested in deepening the mechanisms critically leading to the RG phenotype and hence SH formation. We examined the structural and functional abnormalities of centrosomes, as well as protein transport essential for the formation of the cilia, and identified defects in these processes. Also, we characterized the impact of Eml1 on the progress of the cell cycle in RG and showed S-phase and cell cycle lengthening at early corticogenesis before RG detachment. Using multi-OMICS approches we aim to determine key deregulated genes/proteins and interactions to further explain how subcellular abnormalities and cell cycle alterations cause RG detachment upstream of heterotopia. These data will help propose and test an experimental approach for phenotypic rescue, as well as lead to a better understanding of the understudied role of Eml1 in RG behavior, the latter highly regulated during brain evolution.

INCREASED EXPRESSION OF EHMT1/GLP PROTEIN IN EMBRYONAL NEUROGENESIS, AND SPECIFIC POSTNATAL AND ADULT MOUSE AND RAT BRAIN NEUROGENESIS AREAS

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Catharina Van Der Zee[1], Hans Van Bokhoven[2]
[1]Radboudumc, Cell Biology, Nijmegen, Netherlands, [2]Radboudumc, Genetics, Nijmegen, Netherlands

Euchromatin histone methyltransferase 1 (Ehmt1) is a protein which regulates transcription by catalyzing methylation of histones, which then can lead to silencing of gene expression. Haploinsufficiency of the EHMT1 gene, with only 1 functional allele for the Ehmt1/GLP protein, results in humans in a congenital intellectual disability syndrome called Kleefstra Syndrome. Mice with a heterozygous mutation for Ehmt1 (*Ehmt1+/-*) proved to be an excellent animal model to study Kleefstra Syndrome (Balemans et al. 2010, 2013, 2014 and Iacono et al. 2018). Balemans et al. (2013) showed for *Ehmt1+/-* mice that Ehmt1 protein levels in brain cortex, hippocampus, cerebellum and olfactory bulb are 50% lower than levels measured in littermate wildtype mice, using quantitative Western Blot analysis. In this study, we focused on wildtype brain and demonstrated Ehmt1 protein expression in all cells in all parts of mouse and rat brain. Notably, embryonal stage shows high expression, in the postnatal phase the expression decreases, and in adult brain there is a lower, but apparent Ehmt1 protein expression. Interestingly, significantly elevated Ehmt1 protein levels were found in the two known adult rodent neurogenesis areas: the Dentate Gyrus Subgranular layer and the subventricular zone-RMS-Olfactory bulb areas. A correlation between the number of darkly stained Ehmt1-positive cells and the number of DCX-positive cells in the dentate gyrus subgranular layer and in the subventricular zone / RMS indicates a role for Ehmt1 in adult neurogenesis.

ALDH1L1 DEVELOPMENTAL IMMUNOMORPHOLOGY OF THE FOETAL HUMAN TELENCEPHALON: PRELIMINARY RESULTS

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Ekaterina Tsvetkova, Olga Godovalova, Olga Junemann, Dmitry Otlyga, Alexandra Proshchina, Anastasia Kharlamova
Research Institute of Human Morphology, Laboratory Of Nervous System Development, Moscow, Russian Federation

ALDH1L1 is a specific astrocyte antigen of the mammalian adult brain with a strong pan-astrocyte expression. To better understanding astroglia developmental timeframes in human foetal brain ALDH1L1-immunomorphology analysis was undertaken: foetal human brain autopsies at the prefoetal and early foetal stages (8-20 gestational weeks (gw)) had been studied. ALDH1L1-immunoreactive astroblasts were demonastrated in the basal telencephalon (diagonal band and substantia innominata), ventral striatum (globus pallidus), paleocortical area at the 13-14gw. Only separate immunoreactive fibres were shown in the ventricular zone of ganglionic eminence (GE) at this stage. As gestational weeks increase ALDH1L1-immunoreactive cells were registered through the whole GE, neostriatal and amygdalar areas. Expansion into pallial structures began from the ventrical (vz) and subventrical (svz) zones at 18gw, including paleocortical ventricle. At the beginning of middle foetal period (21-23 gw) numerous ALDH1L1-astrocytes were demonstrated by the neocortical vz-svz and intermediate zone, cortical plate and subcortical zone also demonstrated ALDH1L1-immunoreactivity, but to a lesser extent. Reginal and temporal expansion of ALDH1L1-immunoreactivity in the human foetal telencephalon differs from the GFAP-immunoreactivity patterns (Kharlamova et al., 2018). ALDH1L1-immunoreactive neuroblasts and fibers appeared prior to GFAP-immunoreactivity pattern in the human foetal telencephalon, insular cortex and neocortex became ALDH1L1-immunoreactive also earlier. ALDH1L1-immunomorphological profile evidence for ALDH1L1-astroblasts expansion from the basal (ventral) subpallial structures and paleocortex, into the dorsal extent – dorsal (neo) striatum and cortical areas, whereas GFAP-immunoreactivity firstly appears in the dorsal archaecortical anlag and fimbria, lateral migratory curve and paleocortical marginal zone. This study is supported by the RSF grant # 22-25-00370

OMEGA-3-DERIVED ENDOCANNABINOIDS PREVENT PRO-INFLAMMATORY CYTOKINE-INDUCED DECREASES IN HUMAN HIPPOCAMPAL NEUROGENESIS AND ASTROGLIOGENESIS, AND INCREASE IN APOPTOSIS

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Gargi Mandal, Carmine Pariante, Alessandra Borsini
King's College London, Stress, Psychiatry, And Immunology Lab, Psychological Medicine, London, United Kingdom

Eicosapentaenoyl ethanolamide (EPEA) and Docosahexaenoyl ethanolamide (DHEA) are omega−3−derived endocannabinoids, synthesised from eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), respectively. This study investigated whether EPEA and DHEA treatment prevented the detrimental changes induced by treatment with interleukin−1−beta (IL1-beta) and interleukin−6 (IL6) on neurogenesis, astrogliogenesis, and apoptosis. Human hippocampal progenitors were treated with IL1−beta/IL6 alone or with EPEA/DHEA for 48hrs during differentiation. Doublecortin (DCX)+ neuroblasts, microtubule-associated protein−2 (MAP2)+ neurons, S100 calcium−binding protein−beta (S100−beta)+ astrocytes, and cleaved caspase−3 (CC3)+ apoptotic cells were detected using immunocytochemistry. Treatment with EPEA and DHEA prevented IL1−beta−induced decreases in DCX+ (IL1−beta +EPEA vs IL1−beta: +73.36%, p<0.0001; IL1−beta +DHEA vs IL1−beta: +70.78%, p<0.0001) and MAP2+ (IL1−beta +EPEA vs IL1−beta: +89.32%, p<0.0001; IL1−beta +DHEA vs IL1−beta: +81.38%, p<0.0001), and increase in CC3+ cells(IL1−beta +EPEA vs IL1−beta: −53.05%, p<0.0001; IL1−beta +DHEA vs IL1−beta: −54.67%, p<0.0001). EPEA and DHEA did not prevent IL1−beta−mediated decrease in S100−beta + cells (IL1−beta +EPEA vs IL1−beta: −3.6%, p>0.9999; IL1−beta +DHEA vs IL1−beta: −1.6%, p>0.9999). Treatment with EPEA and DHEA prevented IL6−induced decreases in DCX+ (IL6+EPEA vs IL6: +123.4%, p<0.0001; IL6+DHEA vs IL6: +124.18%, p<0.0001), and S100−beta+ cells(IL6+EPEA vs IL6: +113%, p<0.0001; IL6+DHEA vs IL6: +118.67%, p<0.0001). Only DHEA prevented IL6−induced reduction in MAP2+ (IL6+EPEA vs IL6: +4.8%, p>0.9999; IL6+DHEA vs IL6: +67.12%, p<0.0001), and only EPEA prevented IL6−induced increase in CC3+cells (IL6+EPEA vs IL6: −40.43%, p<0.0001; IL6+DHEA vs IL6: +2.85%, p>0.9999). Our findings demonstrate the anti−inflammatory and neuroprotective roles of EPEA and DHEA against IL1−beta and IL6, and further investigations will discern the underlying mechanisms.

ROLE OF DIAPH3 IN NEURAL STEM CELL BIOLOGY AND TUMOR DEVELOPMENT.

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Rana Saade[1], Georges Chehade[1], Fadel Tissir[1,2]
[1]Université catholique de Louvain (UCLouvain), Institute Of Neuroscience, Laboratory Of Developmental Neurobiology, Brussels, Belgium, [2]Hamad Bin Khalifa University, College Of Health And Life Sciences, Doha, Qatar

Diaphanous(DIAPH)3 belongs to a family of dimeric multidomain proteins called formins that are master regulators of the cytoskeleton in basic cellular processes.In the brain,Diaph3 is specifically expressed in neural stem cells(NSC)and plays an important role during cytokinesis and karyokinesis.Conditional inactivation of Diaph3 in mouse cerebral cortex leads to massive loss of neural progenitors disrupting neurogenesis and causing apoptosis,aneuploiody and microcephaly.We co-inactivated Diaph3 and p53 in dorsal telencephalon by crossing Diaph3/p53 double-floxed mice with Emx1-Cre mice.We report that p53 loss partially restored the disrupted cortical layering and changed the fate of NSCs observed due to Diaph3 loss.We also show that the level of neuronal death observed in Diaph3 single-knockouts was partly rescued by p53 inactivation.However,cells that escape death undergo neoplastic transformation and double mutant mice develop brain tumors with reduced survival.These tumors are identified as Glioblastoma(GBM),the most frequent and aggressive malignant primary brain tumor with a median survival of 15 months in humans.Preliminary studies of animals bearing early olfactory bulb(OB)tumors show that proliferation is increased in the OB and the sub-ventricular zone(SVZ)of the tumoral hemisphere compared to the normal hemisphere.Ongoing studies aim at further analysing the SVZ and the rostral migratory stream(RMS)to detect changes in the fate of NSC and characterize early stages of gliomagenesis as well as generate new markers of GBM as it develops.So far,most of transcriptomic analyses were performed on advanced stages of GBM when the tumor causes detectable behavioral changes.We will combine our mouse models with ultra-high field MRI to compare early stages of GBM and better classify tumors reducing grade-related variability.

REPROGRAMMING MULLER GLIA TO REGENERATE GANGLION CELLS IN ADULT MOUSE RETINA WITH DEVELOPMENTAL TRANSCRIPTION FACTORS.

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Levi Todd, Wesley Jenkins, Fred Rieke, Thomas Reh
University of Washington, Biological Structure, Seattle, United States of America

Mammals are unable to regenerate retina. However, vertebrate species such as zebrafish can regenerate a functional retina after injury. In fish, this feat is accomplished by Muller glia (MG). MG in fish respond to injury by reprogramming into neurogenic progenitors that replace lost neurons and eventually restore vision. Our lab has made progress in engineering MG to regenerate neurons in the adult mouse retina in vivo. This was accomplished by designing MG to overexpress Ascl1, a proneural transcription factor required for zebrafish retinal regeneration. We demonstrated that overexpression of Ascl1 can stimulate MG to produce retinal neurons that functionally integrate into circuity. Thus, adding a single proneural gene is sufficient to initiate a “fish-like” regenerative program in mouse. However, in these initial studies, we found that with Ascl1 alone, MG primarily regenerated a single type of neuron called bipolar cells. We hypothesized that the transcription factor used to stimulate reprogramming may bias the neuronal subtype regenerated. In this study, we report a regeneration strategy combining Ascl1 with developmental transcription factors known to specify retinal ganglion cell fate, Pou4f2 and Iselt1. We find the addition of these two transcription factors improves the neurogenic efficacy and shifts the neuronal fate of reprogrammed MG. Using scRNA-seq, scATAC-seq, immunohistochemistry, and electrophysiology we demonstrate that Pou4f2, Islet1, and Ascl1 can stimulate MG to regenerate retinal ganglion-like neurons in vivo in the adult mouse retina. This work provides a proof-of-principle that developmental transcription factors can be redeployed to guide regeneration to specific subtypes of neurons.

APC/C-CDH1 REGULATES MYELINATION AFTER BIRTH

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Silvia Gomila[1,2], Verónica Bobo-Jiménez[1,2], Rebeca Lapresa[1,2], Jesús Agulla[1,2], Ángeles Almeida[1,2]

Aims The E3 ubiquitin ligase APC/C-Cdh1 plays a key role in the developing brain, where it regulates the onset of neurogenesis during gestation. Whereas neurogenesis is complete at birth, oligodendrogenesis and myelination occur during postnatal brain development. Both processes are temporally regulated by protein turnover via ubiquitination and proteasomal degradation. Then, APC/C-Cdh1 might have a dual function in both pre and postnatal developmental stage. Here, we study the role of APC/C-Cdh1 activity on oligodendroglial lineage and myelination in the postnatal brain. **Methods** We generated Nestin-Cre Cdh1 cKO mice and oligodendrogenesis, myelination, and myelin sheaths were analyzed by electron microscopy, immunohistochemistry, and western blotting at different postnatal days (P0-P21). **Results** Cdh1 deletion resulted in brain morphology alterations, including microcephaly, hydrocephalus, and corpus callosum dysgenesis. Cdh1 loss induced hypomyelination, as revealed by the decreased in myelin (MBP) staining in P14 Cdh1 cKO mice. Myelin ultrastructure analysis at P21 revealed a higher percentage of unmyelinated axons and an increased g-ratio in Cdh1 cKO mice, in comparison to control. Moreover, Cdh1 loss triggered myelin sheath decompaction and disruption, compromising axon integrity and brain function. Finally, the lack of Cdh1 impaired the balance between immature and mature myelinating oligodendrocytes, suggesting a key role of the APC/C-Cdh1 complex in oligodendrogenesis process. **Conclusions** APC/C-Cdh1 activity regulates postnatal myelination, which highlights the impact of Cdh1 in the pathogenesis of neurodevelopmental myelin disorders. Adult neural stem cells (NSCs) dwell in specialized microenvironments called niches, being the most studied the subependymal zone along the lateral ventricles, and the subgranular zone of the dentate gyrus. Despite being mainly quiescent, NSCs can be transiently activated by specific signals to proliferate, but they also can re-enter a state of inactivation to avoid exhaustion. The total pool of NSCs and progenitors at a given time point is a consequence of a set of cellular decisions that control quiescence vs. activation, expansion and terminal differentiation. Whether the instructions that guide the making of these decisions are determined by intrinsic properties, by the microenvironment of the niche or a combination of signals is the subject of intense investigation. Deciphering the molecular players that control NSC activation and mode of division is key to understanding adult neurogenesis, and to open a window to develop therapeutic strategies based on the endogenous reparative potential of the neural tissue, especially in the case of brain injury. Polo-like kinase 1 (Plk1) is a serine/threonine kinase with a key role in mitosis regulation. Plk1 has been linked to the regulation of embryonic NSC and progenitor cells mode of division, but to date, whether Plk1 plays a role in mammalian adult NSC division remains unstudied. Our results indicate that Plk1 is a novel intrinsic regulator of NSCs activation and provide evidence of a molecular link between Plk1 and a master regulator of neurogenesis, through which we propose Plk1 controls activation and neuronal differentiation of NSC.

During neurodevelopment, neurogenesis and gliogenesis are molecularly controlled by transcription factor-mediated interactions. In the mouse cortex, a common pool of progenitors is temporally regulated such that neurogenesis precedes gliogenesis. However, the mechanisms regulating this process during development are not fully understood. Transcription factor Forkhead Box G1 (FOXG1) is known to repress cell cycle exit in the telencephalic progenitors, promote progenitor proliferation and suppress premature differentiation during neurogenesis. We show that Cre-mediated deletion of Foxg1 by *in utero electroporation*, during peak neurogenesis (upper layer neurogenesis), results in premature gliogenesis. In order to lineage trace the progenitors undergoing this cell-fate switch, we use the Mosaic Analysis with Double Marker (MADM) strategy. We identified candidate genes that are possible FOXG1 targets in progenitors, using transcriptomic and transcription factor ChIP-seq analyses from the literature. We find evidence that FOXG1 may act via FGF signaling to control astrogliogenesis, in the neocortical primordium. Our results extend the diverse roles of this transcription factor in neurodevelopment.

The human spinal cord has highly diverse cell types, which are generated during development, governed by a series of temporal and spatial events for proper spinal cord assembly and function. However, the molecular regulation of cell fate specification in the human developing spinal cord remains largely unknown. Here, by performing state-of-the-art multi-omics techniques, including single-cell RNA sequencing, spatial transcriptomics and in situ sequencing, we integrate the datasets and provide a comprehensive single-cell and spatial transcriptomic atlas of the developing human spinal cord of the first trimester, from postconceptional week 5 to 12. We observe that all major cell populations in human adult spinal cord have been specified within the first trimester with abundant cell states, and identify the key genes associated with cell fate choices and their spatial expression. Unexpectedly, we find that during early cell fate specification, many human neural progenitor cells have lost their self-renewal capacity. Further, we discover genetic regulation of cell fate specification is different between rodent and human. Finally, we demonstrate how to use our developmental map for molecular cues that direct sequential cellular differentiation and define cells and locations associated to both normal development and spinal cord diseases.

Normal development of the mammalian central nervous system requires correct tissue patterning, production of the appropriate cell types and establishment of functional neuronal circuits. Transcription factors (TFs) play essential roles in these processes, regulating the expression of target genes responsible for neuronal subtypes specific features. Cell adhesion molecules are key components of neuronal identities that control cell sorting, migration, neurite outgrowth/guidance and synaptogenesis. So far, TFs are known to control neuronal adhesion but not the opposite. Here, using acute gain- and loss-of-function experiments by *in utero* electroporation in the developing mouse telencephalon we demonstrate that ectopic expression of Dbx1, a homeodomain TF acting as a cell fate determinant, leads to increased expression of Protocadherin 8 (*Pcdh8*) and cell aggregation, together with the induction of neuronal fate markers Nurr1 and Pax6. These effects were modulated depending on the region and timing of electroporation. Furthermore, we found that *Pcdh8* expression is required for Dbx1-induced fate specification. Surprisingly, *Pcdh8* overexpression also proved sufficient to induce Dbx1 expression as well as a complete reorganisation of the apico-basal and dorso-ventral axes. Finally, we present evidence that these effects are mediated through regulation of the expression of Notch ligands and promotion of cell cycle exit. Altogether, our work therefore points to cell adhesion molecules as important, yet unexpected, players in the regulation of cell identity and, in particular, Pcdh8 through its crossregulation with the Dbx1 transcription factor.

Diabetic retinopathy is one of the leading causes of blindness in the world. While there is a major focus on the study of adult diabetic retinopathy, the effects of hyperglycemia during early retinal development are less well studied. Recent work in zebrafish revealed that nutritional hyperglycemia leads to decreased numbers of mature retinal cell types, which was related to an increase in apoptotic cell death and altered cell differentiation (Titialii-Torres and Morris, 2022). However, whether embryonic hyperglycemia impacts cell proliferation in developing zebrafish retinas is unknown. We exposed zebrafish embryos to 50 mM glucose from 10 hours postfertilization to 5 days postfertilization (dpf). We confirmed that hyperglycemia increases apoptotic cell death and decreases rod numbers in the retina at 5 dpf. Interestingly, the increased cell death was mainly observed in the peripheral retina, where most of the progenitor cells lie. To analyze the impact of hyperglycemia in cell proliferation, we quantified mitotic activity using pH3 immunolabeling. We observed a significant decrease in mitotic cells (mainly in the peripheral retina) at 5 dpf. The use of the proliferation marker PCNA also allowed us to detect a decrease in cell proliferation in the outer nuclear and ganglion cell layers of the central retina in hyperglycemic animals. Our results show that nutritional hyperglycemia inhibits cell proliferation in the developing retina, which could be an important contributor to the decrease in mature retinal cell types. MIGRATORY NEURONS OF THE HUMAN CEPHALIC ECTODERM AND THE NEURAL CREST

POSTER SESSION 06 - SECTION: NEURAL STEM CELLS, PROLIFERATION & CELL-FATE

Irina Bystron
University of Oxford, Department Of Physiology, Anatomy And Genetics, Oxford, United Kingdom

We report here previously unknown early neuronal populations in humans found outside the brain which have not been described in any other mammalian species.We used a set of neuronal and proliferative markers to reveal the phenotypic characteristic and migratory potential of the earliest neurons of the cephalic ectoderm and the neural crest
We were able to reconstruct cells by high-resolution volume rendering of multichannel 3D data sets from a Zeiss confocal microscope.
Embryos from Carnegie stages (CS) 10-14 (29-33 days post-conception) were obtained from the Human Developmental Biology Resource UK. The preplacodal cephalic epithelium is continuous with the prosencephalic neuroepithelium prior to the fusion of the anterior neuropore. The nasal epiblastic thickening appears at CS11, lateral to the rostral neuropore. By CS12, the major divisions of the brain and the neurogenic placodes are already detectable on the basis of morphological features. The placodal field epithelium is, not mitotically active, with few H3- positive cells restricted to the apical surface of the pseudostratified ectoderm. Notably, we found bipolar TU-20-positive neurons migrating alone several regions of the early cephalic ectoderm, and in mesenchyma adjacent to the oral ectoderm and the neural crest in diencephalon. Some of the TU-20-positive neurons of ectodermal origin migrate into the periocular mesenchyma and extend processes into the eye cup, perhaps providing additional signals to the local stem cell niche. Others invade the cerebral wall of the rostral telencephalon. Thus, the early human cephalic epithelium contains previously unrecognized stem cells generating early migratory neurons that interact with retina and presumptive
cortex. Supported by Knowledge Foundation, The Zvi and Ofra Meitar Family Fund, and Arsenoy Foundation.

NEOCORTICAL INHIBITORY SYNAPTIC NETWORKS REFLECT PYRAMIDAL NEURON LINEAGE

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Gemma Gothard, Kashif Mahfooz, Matthew Buchan, Colin Akerman
University of Oxford, Department Of Pharmacology, Oxford, United Kingdom

The mammalian neocortex comprises a diverse range of excitatory and inhibitory neuron types. An important question in neuroscience is how the connectivity logic within and between these different cell types is able to generate the processing capabilities of cortical circuits. A growing body of research has investigated how excitatory neurons derived from defined progenitor pools during embryonic development exhibit specific synaptic connectivity patterns in the adult cortex [1-4]. Here we examine excitatory and inhibitory synaptic inputs to cortical L2/3 pyramidal neurons derived from apical intermediate progenitors (aIP-derived) and compare these with neighbouring L2/3 pyramidal neurons derived from other progenitors (OP-derived). By combining in utero labelling methods in mice with paired patch clamp electrophysiological recordings in postnatal brain slices, our experiments reveal that aIP-derived neurons share fewer of their inhibitory synaptic inputs with neighbouring neurons, when compared to either OP-derived or unlabelled neurons. Additionally, the amplitude of shared inhibitory input to aIP-derived neurons was lower than that observed in OP-derived and unlabelled neurons. In contrast, aIP-derived neurons shared similar levels of excitatory synaptic input with other neighbouring neurons. These data suggest that the way in which a cortical pyramidal neuron couples to its local inhibitory synaptic network is reflective of the neuron's progenitor of origin.

Correlated spontaneous activity occurs in certain systems of the developing mammalian brain during the early postnatal period and is thought to be crucial for the establishment of precise and mature neural circuits following Hebbian principles of plasticity. In the mouse somatosensory system, the barrel cortex shows patchwork-type spontaneous activity during the first postnatal week (Mizuno et al., 2018, Nakazawa et al., 2020). Previous studies suggested that the source of this activity is in the periphery but downstream of the whisker pad (Mizuno et al., 2018), based on which we hypothesized that the trigeminal ganglion (TG) is the source of spontaneous activity in the neonatal barrel cortex. To examine whether the neonatal TG shows spontaneous activity or not, we established a system for imaging activity in the TG *ex vivo*. We identified the whisker-innervating region in the TG by application of DiI to the whisker pads. Using a transgenic mouse line expressing a genetically encoded calcium indicator (GCaMP6s) in the TG neurons and the *ex vivo* calcium imaging system, we found that the neurons in the whisker-innervating region of P4-P6 mouse TG fire spontaneously. This activity originated within the TG itself and was blocked by the chelation of extracellular calcium. Spontaneous activity was also detected in P0-P1 TG but was largely diminished in the adult TG. The spontaneous activity in the TG during the first postnatal week may contribute to thalamocortical circuit refinement as the source of patchwork-type spontaneous activity in the neonatal mouse barrel cortex.

During the first post-natal week in-vivo, the immature hippocampus is characterized by spontaneous network activity (SNA), often preceded by myoclonic twitches. While it is believed that these SNAs play an important role in the establishment of neural networks, the underlying mechanisms are poorly understood. We performed electrophysiological recordings of the dorsal CA1 region of the hippocampus in unanesthetized mice from post natal day (P) 4 to 8. At P4, while 48% of hippocampal pyramidal cell layer neurons fired strongly at the SNA onset, 23% fired moderately at the offset and 29% do not change their activity. In contrast, below the pyramidal cell layer (str. radiatum+ str moleculare) 81% of neurons are of the onset type, 5% offset and 14% unresponsive. With age, the proportion of onset neurons decreased in all hippocampal layers, leaving place, at P8 to a majority of unresponsive neurons. We then used optogenetcis to identify and characterise the extracellular activity GABAergic neurons. Preliminary data suggest that GABAergic cells located above and within the pyramidal cell layer are only moderately active during SNAs. The investigation of GABAergic cells below the pyramidal layer is still in progress. The fact that neurons located below the pyramidal cell layer are amongst the most strongly activated during SNAs suggests that they play an important role in the establishment of hippocampal networks. We are now characterising their cellular subtype using optogenetics.

During neurodevelopment, a critical time window defines the striatum neuronal network maturation, and any impairments in this critical period may lead to neurodevelopmental movement disorders. Due to heterogeneity of striatal spiny projection neurons (SPNs), precise identification of the critical time window for striatum is complicated. We characterized the spatial and temporal profile of neonatal spontaneous activity in the striatum. Using neonatal Drd1a-Cre/tdTomato and Adora2a-Cre/tdTomato mice, we demonstrated a clustered organization of fluorescent direct-pathway SPNs (dSPNs) and indirect-pathway SPNs (iSPNs), which correspond to striosomes. Using *in vitro* electrophysiological recordings, we evaluated domain-specific intrinsic excitability and passive membrane properties of SPNs. Our data show that neuronal activity in developing striatum depends on age and domain. The age-dependent spontaneous activity was more evident in striosomes than in matrix SPNs. In both compartments, iSPNs retained this activity longer than dSPNs. Next, we investigated the role of the SPNs' spontaneous activity in the maturation of the basal ganglia network. We injected at P0 a viral vector to induce expression of the inhibitory DREADDs that specifically respond to clozapine-N-oxide (CNO) in striosomal dorsal striatum SPNs of Oprm1-Cre mice and suppress neuronal activity in neonatal mice. The results show that suppression of spontaneous activity of striosomal SPNs during prospective critical time window causes a significant and persistent decrease in the frequency of the miniature inhibitory postsynaptic currents (mIPSCs) in substantia nigra pars compacta dopaminergic neurons of CNO injected adult mice. These results elucidate the mechanisms possibly underlying neurodevelopmental movement disorders linked to striatal functions.

During the first postnatal week of rodents, behaviors such as nipple attachment, orientation and approach to the nest, and mother attachment learning are significantly influenced by olfaction. Our previous study showed that the end of the sensitive period for mother attachment learning in rats at postnatal day (P) 10 could occur due to the maturation of the electric properties of anterior piriform cortex (aPC) pyramidal (pyr) cells. Specifically, the properties of P5 aPC pyr cells and not those of P14 allow for greater cell recruitment during odor conditioning, and GABAergic synaptic transmission profile at P5 contributes to this. Here, we explore how intrinsic maturational properties of pyr cells and GABAergic synaptic transmission in the aPC might contribute to odor processing at P5 and P14. Using a previous olfactory bulb- aPC computational circuit model for P5 and P14 rat pups, updating the latter with experimental EGABA, we simulated a 3s long odor processing. We found that pyr cells of both ages started to fire during the inhalation phase, with P5 pyr cells showing faster recruitment and rising firing rate, twice higher than P14, followed by a quick suppression during the first 50 ms. P14 pyr cells showed slow recruitment and low-rate firing, which was constant throughout the next 50 ms period, in which their firing rate became twice greater than P5 pyr cells. These results suggest that the intrinsic electrophysiological and synaptic maturation properties of aPC provide a neuronal substrate for distinct odor processing at P5 and P14

DIFFERENTIAL SYNAPTIC INHIBITION PATTERNS ONTO LAYER 5 PYRAMIDAL CELL SUBPOPULATIONS

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Julie Jezequel[1], Tim Kroon[2], Patricia Maeso Hernandez[2], Giuseppe Condomitti[2], Teresa Garces Del Rey[2], Maddalena Balia[2], Beatriz Rico[2]
[1]King's College London, Mrc Centre For Neurodevelopmental Disorders, Centre For Developmental Neurobiology, London, United Kingdom, [2]King's College London, Mrc Centre For Neurodevelopmental Disorders, Centre For Developmental Neurobiology, LONDON, United Kingdom

In the mammalian neocortex, excitatory pyramidal cells (PC) are assembled in distinct subnetworks, receiving inputs from various sources and projecting outputs to different brain areas. Cortical layer 5 (L5) represents a textbook example of this intricate organisation, where distinct PC subpopulations coexist within the same environment. GABAergic inhibitory interneurons (INs), by providing local inhibition, ensure a proper computation of these multiple information processing streams. While INs were long thought to provide unbiased inhibition onto nearby PC, recent work gathered strong evidence of cell-specific inhibitory connectivity. However, how and when GABAergic INs precisely target and regulate such intermingled excitatory subpopulations remains unclear. Using a combination of viral-based retrograde tracing, transcriptomics and synaptic analysis, we investigated the molecular rules underlying PC subtype-specific inhibition during cortical development. First, we characterised the dynamics of INs synaptic connectivity onto L5 PC subpopulations. Our data demonstrate that neighbouring L5 cortico-cortical and cortico-pontine PC, while residing in the same layer, receive specific combinations of inhibitory inputs. These differential synaptic inhibition patterns emerge early in development and are likely instructed by molecular programs unique to these PC subtypes. Next, we explored how genetic manipulations in vivo could reshape these specific synaptic connectivity motifs onto L5 PC subpopulations. Altogether, our work suggests that PC identity is a crucial determinant of inhibitory circuits assembly.

Alteration of NMDA receptor trafficking as a cellular hallmark of psychosis.
A dysfunction of the glutamatergic transmission, especially of the NMDA receptor (NMDAR), constitutes one of the main biological substrate of psychotic disorders, such as schizophrenia. The NMDAR signaling hypofunction, through genetic and/or environmental insults, would cause a neurodevelopmental myriad of molecular, cellular, and network alterations that persist throughout life. Yet, the mechanisms underpinning NMDAR dysfunctions remain elusive. Here, we compared the membrane trafficking of NMDAR in three gold-standard models of schizophrenia, i.e., patient's cerebrospinal fluids, genetic manipulations of susceptibility genes, and prenatal developmental alterations. Using a combination of single nanoparticle tracking, electrophysiological, biochemical, and behavioral approaches in rodents, we identified that the NMDAR trafficking in hippocampal neurons was consistently altered in all these different models. Artificial manipulations of the NMDAR surface dynamics with competing ligands or antibody-induced receptor cross-link in the developing rat brain were sufficient to regulate the adult acoustic startle reflex and compensate for an early pathological challenge. Collectively, we show that the NMDAR trafficking is markedly altered in all clinically relevant models of psychosis, opening new avenues of therapeutical strategies.

Distinct molecular programs regulate synapse specificity in cortical inhibitory circuits.
How neuronal connections are established and organized into functional networks determines brain function. In the mammalian cerebral cortex, different classes of GABAergic interneurons exhibit specific connectivity patterns that underlie their ability to shape temporal dynamics and information processing. Much progress has been made toward parsing interneuron diversity, yet the molecular mechanisms by which interneuron-specific connectivity motifs emerge remain unclear. In this study, we investigated transcriptional dynamics in different classes of interneurons during the formation of cortical inhibitory circuits in mouse. We found that whether interneurons form synapses on the dendrites, soma, or axon initial segment of pyramidal cells is determined by synaptic molecules that are expressed in a subtype-specific manner. Thus, cell-specific molecular programs that unfold during early postnatal development underlie the connectivity patterns of cortical interneurons.

Tracking single membrane targets of human autoantibodies using single nanoparticle imaging.
Over the past decade, an increasing number of neurological and neuropsychiatric diseases have been associated with the expression of autoantibodies directed against neuronal targets, including neurotransmitter receptors. Although cell-based assays are routinely used in clinics to detect the presence of immunoglobulins, such tests often provide heterogeneous outcomes due to their limited sensitivity, especially at low titers. Thus, there is an urging need for new methods allowing the detection of autoantibodies in seropositive patients that cannot always be clinically distinguished from seronegative ones.

Dynamic disorganization of synaptic NMDA receptors triggered by autoantibodies from psychotic patients.
The identification of circulating autoantibodies against neuronal receptors in neuropsychiatric disorders has fostered new conceptual and clinical frameworks. However, detection reliability, putative presence in different diseases and in health have raised questions about potential pathogenic mechanism mediated by autoantibodies. Using a combination of single molecule-based imaging approaches, we here ascertain the presence of circulating autoantibodies against glutamate NMDA receptor (NMDAR-Ab) in about 20% of psychotic patients diagnosed with schizophrenia and very few healthy subjects. NMDAR-Ab from patients and healthy subjects do not compete for binding on native receptor. Strikingly, NMDAR-Ab from patients, but not from healthy subjects, specifically alter the surface dynamics and nanoscale organization of synaptic NMDAR and its anchoring partner the EphrinB2 receptor in heterologous cells, cultured neurons and in mouse brain. Functionally, only patients' NMDAR-Ab prevent long-term potentiation at glutamatergic synapses, while leaving NMDAR-mediated calcium influx intact. We unveil that NMDAR-Ab from psychotic patients alter NMDAR synaptic transmission, supporting a pathogenically relevant role.
Nat Commun, 2017; 8
28780967: Jézéquel J, Rogemond V, Pollak T, Lepleux M, Jacobson L, Gréa H, Iyegbe C, Kahn R, McGuire P, Vincent A, Honnorat J, Leboyer M, Groc L
Cell- and Single Molecule-Based Methods to Detect Anti-N-Methyl-D-Aspartate Receptor Autoantibodies in Patients With First-Episode Psychosis From the OPTiMiSE Project.
Circulating autoantibodies against glutamatergic N-methyl-D-aspartate receptor (NMDAR) have been reported in a proportion of patients with psychotic disorders, raising hopes for more appropriate treatment for these antibody-positive patients. However, the prevalence of circulating autoantibodies against glutamatergic NMDAR in psychotic disorders remains controversial, with detection prevalence rates and immunoglobulin classes varying considerably between studies, perhaps because of different detection methods. Here, we compared the results of serum assays for a large cohort of patients with first-episode psychosis using classical cell-based assays in three labs and a single molecule-based imaging method. Most assays and single molecule imaging in live hippocampal neurons revealed the presence of circulating autoantibodies against glutamatergic NMDAR in approximately 5% of patients with first-episode psychosis. However, some heterogeneity between cell-based assays was clearly observed, highlighting the urgent need for new sensitive methods to detect the presence of low-titer autoantibodies against glutamatergic NMDAR in seropositive patients who cannot be clinically identified from

seronegative ones.

27831563: Lesept F, Chevilley A, Jezequel J, Ladépêche L, Macrez R, Aimable M, Lenoir S, Bertrand T, Rubrecht L, Galea P, Lebouvier L, Petersen KU, Hommet Y, Maubert E, Ali C, Groc L, Vivien D
Tissue-type plasminogen activator controls neuronal death by raising surface dynamics of extrasynaptic NMDA receptors.
N-methyl-d-aspartate receptors (NMDARs) are ion channels whose synaptic versus extrasynaptic localization critically influences their functions. This distribution of NMDARs is highly dependent on their lateral diffusion at the cell membrane. Each obligatory subunit of NMDARs (GluN1 and GluN2) contains two extracellular clamshell-like domains with an agonist-binding domain and a distal N-terminal domain (NTD). To date, the roles and dynamics of the NTD of the GluN1 subunit in NMDAR allosteric signaling remain poorly understood. Using single nanoparticle tracking in mouse neurons, we demonstrate that the extracellular neuronal protease tissue-type plasminogen activator (tPA), well known to have a role in the synaptic plasticity and neuronal survival, leads to a selective increase of the surface dynamics and subsequent diffusion of extrasynaptic NMDARs. This process explains the previously reported ability of tPA to promote NMDAR-mediated calcium influx. In parallel, we developed a monoclonal antibody capable of specifically blocking the interaction of tPA with the NTD of the GluN1 subunit of NMDAR. Using this original approach, we demonstrate that the tPA binds the NTD of the GluN1 subunit at a lysine in position 178. Accordingly, when applied to mouse neurons, our selected antibody (named Glunomab) leads to a selective reduction of the tPA-mediated surface dynamics of extrasynaptic NMDARs, subsequent signaling and neurotoxicity, both in vitro and in vivo. Altogether, we demonstrate that the tPA is a ligand of the NTD of the obligatory GluN1 subunit of NMDAR acting as a modulator of their dynamic distribution at the neuronal surface and subsequent signaling.

Ultradian corticosterone pulses balance glutamatergic transmission and synaptic plasticity.
The rodent adrenal hormone corticosterone (CORT) reaches the brain in hourly ultradian pulses, with a steep rise in amplitude before awakening. The impact of a single CORT pulse on glutamatergic transmission is well documented, but it remains poorly understood how consecutive pulses impact on glutamate receptor trafficking and synaptic plasticity. By using high-resolution imaging and electrophysiological approaches, we report that a single pulse of CORT to hippocampal networks causes synaptic enrichment of glutamate receptors and increased responses to spontaneously released glutamatergic vesicles, collectively abrogating the ability to subsequently induce synaptic long-term potentiation. Strikingly, a second pulse of CORT one hour after the first--mimicking ultradian pulses--completely normalizes all aspects of glutamate transmission investigated, restoring the plastic range of the synapse. The effect of the second pulse is precisely timed and depends on a nongenomic glucocorticoid receptor-dependent pathway. This normalizing effect through a sequence of CORT pulses--as seen around awakening--may ensure that hippocampal glutamatergic synapses remain fully responsive and able to encode new stress-related information when daily activities start.

Pathogenicity of Antibodies against NMDA Receptor: Molecular Insights into Autoimmune Psychosis.
Recent years have seen a flourishing literature on detection of circulating autoantibodies against neurotransmitter receptors in patients with neuropsychiatric disorders. These studies have generated hope for a better understanding of the underlying molecular dysfunctions and for appropriate therapeutic strategies. However, the detection of these autoantibodies in healthy subjects, and the lack of mechanistic insights have fostered debate about the pathogenic role of such autoantibodies. Here, we specifically discuss the biological evidence linking autoantibodies directed against the glutamatergic N-methyl-d-aspartate (NMDA) receptor (NMDAR-Abs) and psychosis, emphasising recent single-molecule imaging investigations that unveiled the impaired surface trafficking of NMDAR in the presence of NMDAR-Abs from psychotic patients. Although still in its infancy, the hypothesis that NMDAR-Abs from patients with psychosis play a pathogenic role is thus gaining support, opening avenues of fundamental and translational investigations.

EXAMINING DENDRITIC PLASTICITY OF THE BARREL CORTEX LAYER 4 NEURONS VIA IN VIVO HIGH SPATIOTEMPORAL-RESOLUTION IMAGING

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Luwei Wang[1,2], Shingo Nakazawa[1], Hidenobu Mizuno[3], Takuji Iwasato[1,2]

The specific arborization of dendrites determines the inputs the neuron receives, and the accurate dendritic patterns are formed and refined during development in an activity-dependent manner. It is crucial to understand how dendrites elaborate and refine their morphologies during development. Our lab has established two-photon time-lapse in vivo imaging approaches in the neonatal mouse brain to investigate the dynamics of dendritic refinement of cortical neurons (Mizuno et al., Neuron 2014; Nakazawa et al., Nature Commun. 2018). However, the spatiotemporal resolutions of these imaging protocols were not sufficiently high. We here increased the temporal resolution of the imaging system from 8-hour interval to 1-hour interval. We also improved the spatial resolution of dendrite morphology imaging by using a membrane-bound RFP (mRFP) instead of a regular RFP. Neurons labeled with the mRFP visualized the more precise dendritic morphologies comparing to the regular RFP. In-utero electroporation-based Supernova (Mizuno et al., 2014; Luo et al., Sci. Rep. 2016) was used to sparsely label barrel cortex L4 neurons with the mRFP. TCA-GFP mice (Mizuno et al., 2014) were used to enable *in vivo* visualization of the barrel map. Then, we imaged dendrites of the same neurons for 8 hours at postnatal day 4, which is in the middle of the dendritic refinement process. With improved in vivo imaging resolution, we were able to detect precise changes of individual dendrites including those of short-lived dendritic trees and branches. Our imaging also identified several transient refinement features of L4 neuron dendrites. Our recent finding will be discussed.

The transcriptional factor Apt regulates neuroblast differentiation through activating CycE expression.
In Drosophila, the thoracic neuroblast 6-4 (NB6-4T) divides asymmetrically into a glial precursor and a neuronal precursor, while the abdominal neuroblast 6-4 (NB6-4A) divides symmetrically to produce two glial cells. The underlying mechanism by which NB6-4T and NB6-4A undergo distinct differentiation is still elusive. Here, we find that the transcription factor Apontic (Apt) exclusively expresses in NB6-4T cells and is involved in regulating NB6-4T differentiation. Loss of Apt results in neuronal precursor loss. Epistasis analysis shows that Apt controls NB6-4T differentiation through activating CycE expression. On the other hand, Gcm suppresses Apt expression in the NB6-4A cell, thus inhibiting CycE expression. Taken together, our findings reveal a Gcm-Apt-CycE axis that regulates neuroblast and glia cell differentiation.

UNRAVELLING THE NATURE OF NEURAL NETWORKS WITH DIFFERENT RATIOS OF INHIBITORY AND EXCITATORY NEURONS

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Eleonora Crocco[1], Greta Ghiloni[2], Federico Cremisi[1]
[1]Scuola Normale Superiore - Pisa, Neuroscience, Pisa, Italy, [2]University of Pisa, Molecular Biology, Pisa, Italy

INTRODUCTION: To make a working nervous system, only two forces are necessary: excitation and inhibition. The impact of different ratios of GABAergic neurons on the functioning of local cortical networks is so far not completely known. Indeed, through the use of mouse embryonic stem cells (mESCs) it is possible to manipulate neurogenesis and develop neural cultures with glutamatergic and GABAergic neurons. **AIM**: In our work, we aimed to design cortical cell cultures with different ratios of inhibitory and excitatory neurons, with the purpose of observing neuronal differentiation, synaptic formation, and neural activity by the use of intracellular Ca^{2+} live imaging. **METHODS**: The achievement of this goal was validated by qRT-PCR, immunocytodetection and calcium imaging experiments. **RESULTS**: With the use of Cyclopamine and SAG (Smoothened Agonist), we established new protocols to create distinct cultures of excitatory and inhibitory neurons, finding 94% of vGlut2 positive neurons and 80% of GAD65 positive neurons, respectively. We then designed cortical cell populations with different E/I (excitation/inhibition) ratios, developing a physiological (80/20) and an experimental condition (50/50). We performed calcium live imaging experiments with the Fluo3 calcium indicator and with a Lentiviral Vector that expresses GcaMP6s, a genetically encoded calcium indicator, under the control of a synaptic-specific promoter. Our preliminary results suggest that cortical networks with different GABAergic:glutamatergic ratios develop connectivity and spontaneous activity that might be influenced by the different ratio. **CONCLUSIONS**: The setup of an *in vitro* method could be useful to functionally study cortical inhibitory networks and activity and plasticity of cortical networks.

SUBTHRESHOLD ACTIVITY MAY REGULATE THE MIGRATION OF CORTICAL 5HT3AR-EXPRESSING INTERNEURONS

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Henna Kallo
University of Helsinki, Neuroscience Center, Helsinki, Finland

During early cortical development, ongoing competition between innate and experience-derived network activity is crucial for the proper functional maturation of the somatosensory system. A prominent feature of this period is the migration of gamma-aminobutyric acid-expressing (GABAergic) interneurons (INs) into the cortical plate. The final steps of IN migration coincide with the rise of K+-Cl- co-transporter (KCC2) expression. Here we studied how migration of 5HT3aR-positive INs in organotypic brain cultures is affected by the manipulation of activity by a sodium channel blocker TTX or KCC2 inhibitor VU0463271 (“VU”). Moreover, we aimed to increase the activity in slices with a lowered concentration of Mg2+ and increased K+ concentration (“MgK”). The impact of the different conditions on network activity was monitored by calcium imaging of Emx1-GCaMP6f mice. Surprisingly, neither MgK nor TTX caused significant alterations in the network activity. Interestingly, in addition to inducing significant reduction of the number of active ROIs, the number of ROIs participating in network events was significantly higher in VU than in control indicating that VU causes synchronization of the subthreshold network activity. Next, we investigated whether the migration of 5HT3aR-expressing INs is affected by this activity. Analysis of saltatory movement indicated reduced motility of 5HT3aR+ INs in organotypic cultures treated with the VU. Migration of INs in slices with TTX or MgK did not differ from the control. These experimental evidence suggests that migration of 5HT3aR+ INs might depend on KCC2 functionality and specific type of network activity. Further studies are required to reveal cell-type specific details.

Voltage-gated calcium channels (VGGC) are crucial for proper neuronal functioning, and therefore have an implicit impact on the network formation of neurons. The VGGC auxiliary α2δ-subunits have been found to regulate synaptic functioning in a variety of ways, notably synaptic organization, and VGGC recruitment. In this project, we aim to evaluate how α2δ3 expression levels affect neuronal networks in their development. We grow our hippocampal dissociated neuronal culture on microelectrode arrays, allowing for non-invasive extracellular recordings over several weeks. We introduce either overexpression or knock-down of α2δ3 via lentiviral infection and perform extracellular recordings every seven days for a period of 30 days. Thus, observing the entire process of network development. With our analysis pipeline, we extract the functional network structure by statistical dependencies between successive action potentials. Subsequently, different graph theoretical measures are used to compare the network to a matched control (e.g., clustering, connectivity). Preliminary results suggest an aberrant connectivity pattern in both conditions (up- and downregulation of α2δ3) in comparison to control conditions. Specifically, α2δ3 seems to influence GABAergic signaling and interneurons stronger than excitatory neurons. Overall, the knock-down of α2δ3 strengthened short-range over long-range connectivity and induced an excitatory to inhibitory imbalance, leading to a connectivity pattern typical of neuropsychiatric disorders, and particularly prominent in autism spectrum disorder.

More than a pore: How voltage-gated calcium channels act on different levels of neuronal communication regulation.
Voltage-gated calcium channels (VGCCs) represent key regulators of the calcium influx through the plasma membrane of excitable cells, like neurons. Activated by the depolarization of the membrane, the opening of VGCCs induces very transient and local changes in the intracellular calcium concentration, known as calcium nanodomains, that in turn trigger calcium-dependent signaling cascades and the release of chemical neurotransmitters. Based on their central importance as concierges of excitation-secretion coupling and therefore neuronal communication, VGCCs have been studied in multiple aspects of neuronal function and malfunction. However, studies on molecular interaction partners and recent progress in omics technologies have extended the actual concept of these molecules. With this review, we want to illustrate some new perspectives of VGCCs reaching beyond their function as calcium-permeable pores in the plasma membrane. Therefore, we will discuss the relevance of VGCCs as voltage sensors in functional complexes with ryanodine receptors, channel-independent actions of auxiliary VGCC subunits, and provide an insight into how VGCCs even directly participate in gene regulation. Furthermore, we will illustrate how structural changes in the intracellular C-terminus of VGCCs generated by alternative splicing events might not only affect the biophysical channel characteristics but rather determine their molecular environment and downstream signaling pathways.

Reliability of genomic variants across different next-generation sequencing platforms and bioinformatic processing pipelines.
Next Generation Sequencing (NGS) is the fundament of various studies, providing insights into questions from biology and medicine. Nevertheless, integrating data from different experimental backgrounds can introduce strong biases. In order to methodically investigate the magnitude of systematic errors in single nucleotide variant calls, we performed a cross-sectional observational study on a genomic cohort of 99 subjects each sequenced via (i) Illumina HiSeq X, (ii) Illumina HiSeq, and (iii) Complete Genomics and processed with the respective bioinformatic pipeline. We also repeated variant calling for the

Illumina cohorts with GATK, which allowed us to investigate the effect of the bioinformatics analysis strategy separately from the sequencing platform's impact.

Mutation of the gene *LIS1* causes lissencephaly, a severe developmental disorder with a deep disorganization of the cerebral cortex. We have studied the consequences of the inactivation of the mouse gene *Lis1* selectively in the neurons expressing parvalbumin (PV). To do that we have breed Lis1KO-flox and PV-cre mouse lines to produce animals (Lis1KO-PV$^+$) in which the *Lis1* gene is inactivated selectively in those neurons expressing PV. In homozygous Lis1KO-PV$^+$ postnatal animals (P14-P18) Nissl staining and NeuN immunohistochemistry showed a disorganized hippocampal CA3 area and the presence of a thin layer of ectopic somas of pyramidal neurons placed in the stratum radiatum / lacunosum of CA3; these ectopic neurons did not express PV. Calbindin staining showed that axons originated in the dentate gyrus reached the area of ectopic neurons. *c-Fos* staining suggested the presence of functional abnormalities since we detected a larger number of *c-Fos* positive neurons in the abnormal CA3 area of mutant animals in comparison with littermate wild type animals (122.0±17.2 and 61.2±11.0 respectively; n=3 for genotype; p=0.007 Student's t test); in contrast, the total number of neurons positive to NeuN in CA3 was similar in mutant and WT animals (335.3±103.7 and 389.4±54.7 respectively; n=3 for genotype; p=0.469 Student's t test). These results show the presence in Lis1KO-PV$^+$ animals of structural and functional abnormalities affecting the hippocampal pyramidal neurons, and suggest the existence of non-cell-autonomous mechanisms that could explain abnormalities in pyramidal neurons after *Lis1* inactivation in PV positive neurons. Cellular and molecular basis of cerebellar development.
Historically, the molecular and cellular mechanisms of cerebellar development were investigated through structural descriptions and studying spontaneous mutations in animal models and humans. Advances in experimental embryology, genetic engineering, and neuroimaging techniques render today the possibility to approach the analysis of molecular mechanisms underlying histogenesis and morphogenesis of the cerebellum by experimental designs. Several genes and molecules were identified to be involved in the cerebellar plate regionalization, specification, and differentiation of cerebellar neurons, as well as the establishment of cellular migratory routes and the subsequent neuronal connectivity. Indeed, pattern formation of the cerebellum requires the adequate orchestration of both key morphogenetic signals, arising from distinct brain regions, and local expression of specific transcription factors. Thus, the present review wants to revisit and discuss these morphogenetic and molecular mechanisms taking place during cerebellar development in order to understand causal processes regulating cerebellar cytoarchitecture, its highly topographically ordered circuitry and its role in brain function.

GAP junctional communication in brain secondary organizers.
Gap junctions (GJs) are integral membrane proteins that enable the direct cytoplasmic exchange of ions and low molecular weight metabolites between adjacent cells. They are formed by the apposition of two connexons belonging to adjacent cells. Each connexon is formed by six proteins, named connexins (Cxs). Current evidence suggests that gap junctions play an important part in ensuring normal embryo development. Mutations in connexin genes have been linked to a variety of human diseases, although the precise role and the cell biological mechanisms of their action remain almost unknown. Among the big family of Cxs, several are expressed in nervous tissue but just a few are expressed in the anterior neural tube of vertebrates.

Many efforts have been made to elucidate the molecular bases of Cxs cell biology and how they influence the morphogenetic signal activity produced by brain signaling centers. These centers, orchestrated by transcription factors and morphogenes determine the axial patterning of the mammalian brain during its specification and regionalization. The present review revisits the findings of GJ composed by Cx43 and Cx36 in neural tube patterning and discuss Cx43 putative enrollment in the control of Fgf8 signal activity coming from the well known secondary organizer, the isthmic organizer.

Cilia, ciliopathies and hedgehog-related forebrain developmental disorders.
Development of the forebrain critically depends on the Sonic Hedgehog (Shh) signaling pathway, as illustrated in humans by the frequent perturbation of this pathway in holoprosencephaly, a condition defined as a defect in the formation of midline structures of the forebrain and face. The Shh pathway requires functional primary cilia, microtubule-based organelles present on virtually every cell and acting as cellular antennae to receive and transduce diverse chemical, mechanical or light signals. The dysfunction of cilia in humans leads to inherited diseases called ciliopathies, which often affect many organs and show diverse manifestations including forebrain malformations for the most severe forms. The purpose of this review is to provide the reader with a framework to understand the developmental origin of the forebrain defects observed in severe ciliopathies with respect to perturbations of the Shh pathway. We propose that many of these defects can be interpreted as an imbalance in the ratio of activator to repressor forms of the Gli transcription factors, which are effectors of the Shh pathway. We also discuss the complexity of ciliopathies and their relationships with forebrain disorders such as holoprosencephaly or malformations of cortical development, and emphasize the need for a closer examination of forebrain defects in ciliopathies, not only through the lens of animal models but also taking advantage of the increasing potential of the research on human tissues and organoids.

Neuronal tangential migration from Nkx2.1-positive hypothalamus.
During the development of the central nervous system, the immature neurons suffer different migration processes. It is well known that Nkx2.1-positive ventricular layer give rise to critical tangential migrations into different regions of the developing forebrain. Our aim was to study this phenomenon in the hypothalamic region. With this purpose, we used a transgenic mouse line that expresses the tdTomato reporter driven by the promotor of Nkx2.1. Analysing the Nkx2.1-positive derivatives at E18.5, we found neural contributions to the prethalamic region, mainly in the zona incerta and in the mes-diencephalic tegmental region. We studied the developing hypothalamus along the embryonic period. From E10.5 we detected that the Nkx2.1 expression domain was narrower than the reporter distribution. Therefore, the Nkx2.1 expression fades in a great number of the early-born neurons from the Nkx2.1-positive territory. At the most caudal positive part, we detected a thin stream of positive neurons migrating caudally into the mes-diencephalic tegmental region using time-lapse experiments on open neural tube explants. Late in development, we found a second migratory stream into the prethalamic territory. All these tangentially migrated neurons developed a gabaergic phenotype. In summary, we have described the contribution of interneurons from the Nkx2.1-positive hypothalamic territory into two different rostrocaudal territories: the mes-diencephalic reticular formation through a caudal tangential migration and the prethalamic zona incerta complex through a dorsocaudal tangential migration.

Role in the Development of the Habenula and the Fasciculus Retroflexus.
is one of the morphogenes that controls the specification and differentiation of neuronal populations in the developing central nervous system. The habenula is a diencephalic neuronal complex located in the most dorsal aspect of the thalamic prosomere. This diencephalic neuronal population is involved in the limbic system and its malfunction is related with several psychiatric disorders. Our aim is to elucidate the role in the habenula and its main efferent tract, the fasciculus retroflexus, development. In order to achieve these objectives, we analyzed these structures development in a lack of function mouse model. The habenula was generated in our model, but it presented an enlarged volume. This alteration was due to an increment in habenular neuroblasts proliferation rate. The fasciculus retroflexus also presented a wider and disorganized distribution and a disturbed final trajectory toward its target. The mid-hindbrain territories that the tract must cross were miss-differentiated in our model. The specification of the habenula is independent. Nevertheless, it controls its precursors proliferation rate. expressed in the isthmic organizer is vital to induce the midbrain and rostral hindbrain territories. The alteration of these areas is responsible for the fasciculus retroflexus axons misroute.

RPGRIP1L is required for stabilizing epidermal keratinocyte adhesion through regulating desmoglein endocytosis.
Cilia-related proteins are believed to be involved in a broad range of cellular processes. Retinitis pigmentosa GTPase regulator interacting protein 1-like (RPGRIP1L) is a ciliary protein required for ciliogenesis in many cell types, including epidermal keratinocytes. Here we report that RPGRIP1L is also involved in the maintenance of desmosomal junctions between keratinocytes. Genetically disrupting the Rpgrip1l gene in mice caused intraepidermal blistering, primarily between basal and suprabasal keratinocytes. This blistering phenotype was associated with aberrant expression patterns of desmosomal proteins, impaired desmosome ultrastructure, and compromised cell-cell adhesion in vivo and in vitro. We found that disrupting the RPGRIP1L gene in HaCaT cells, which do not form primary cilia, resulted in mislocalization of desmosomal proteins to the cytoplasm, suggesting a cilia-independent function of RPGRIP1L. Mechanistically, we found that RPGRIP1L regulates the endocytosis of desmogleins such that RPGRIP1L-knockdown not only induced spontaneous desmoglein endocytosis, as determined by AK23 labeling and biotinylation assays, but also exacerbated EGTA- or pemphigus vulgaris IgG-induced desmoglein endocytosis. Accordingly, inhibiting endocytosis with dynasore or sucrose rescued these desmosomal phenotypes. Biotinylation assays on cell surface proteins not only reinforced the role of RPGRIP1L in desmoglein endocytosis, but also suggested that RPGRIP1L may be more broadly involved in endocytosis. Thus, data obtained from this study advanced our understanding of the biological functions of RPGRIP1L by identifying its role in the cellular endocytic pathway.

Netrin 1-Mediated Role of the Substantia Nigra Pars Compacta and Ventral Tegmental Area in the Guidance of the Medial Habenular Axons.
The fasciculus retroflexus is an important fascicle that mediates reward-related behaviors and is associated with different psychiatric diseases. It is the main habenular efference and constitutes a link between forebrain regions, the midbrain, and the rostral hindbrain. The proper functional organization of habenular circuitry requires complex molecular programs to control the wiring of the habenula during development. However, the mechanisms guiding the habenular axons toward their targets remain mostly unknown. Here, we demonstrate the role of the mesodiencephalic dopaminergic neurons (substantia nigra pars compacta and ventral tegmental area) as an intermediate target for the correct medial habenular axons navigation along the anteroposterior axis. These neuronal populations are distributed along the anteroposterior trajectory of these axons in the mesodiencephalic basal plate. Using and experiments, we determined that this navigation is the result of attraction generated by the mesodiencephalic dopaminergic neurons. This attraction is mediated by the receptor deleted in colorectal cancer (DCC), which is strongly expressed in the medial habenular axons. The increment in our knowledge on the fasciculus retroflexus trajectory guidance mechanisms opens the possibility of analyzing if its alteration in mental health patients could account for some of their symptoms.

Properties of the epileptiform activity in the cingulate cortex of a mouse model of LIS1 dysfunction.
Dysfunction of the LIS1 gene causes lissencephaly, a drastic neurological disorder characterized by a deep disruption of the cortical structure. We aim to uncover alterations of the cortical neuronal networks related with the propagation of epileptiform activity in the Lis1/sLis1 mouse, a model lacking the LisH domain in heterozygosis. We did extracellular field-potential and intracellular recordings in brain slices of the anterior cingulate cortex (ACC) or the retrosplenial cortex (RSC) to study epileptiform activity evoked in the presence of bicuculline (10 μM), a blocker of GABA receptors. The sensitivity to bicuculline of the generation of epileptiform discharges was similar in wild type (WT) and Lis1/sLis1 cortex (EC 1.99 and 2.24 μM, respectively). In the Lis1/sLis1 cortex, we observed a decreased frequency of the oscillatory post-discharges of the epileptiform events; also, the propagation of epileptiform events along layer 2/3 was slower in the Lis1/sLis1 cortex (WT 47.69 ± 2.16 mm/s, n = 25; Lis1/sLis1 37.34 ± 2.43 mm/s, n = 15; p = 0.004). The intrinsic electrophysiological properties of layer 2/3 pyramidal neurons were similar in WT and Lis1/sLis1 cortex, but the frequency of the spontaneous EPSCs was lower and their peak amplitude higher in Lis1/sLis1 pyramidal neurons. Finally, the propagation of epileptiform activity was differently affected by AMPA receptor blockers: CNQX had a larger effect in both ACC and RSC while GYKI53655 had a larger effect only in the ACC in the WT and Lis1/sLis1 cortex. All these changes indicate that the dysfunction of the LIS1 gene causes abnormalities in the properties of epileptiform discharges and in their propagation along the layer 2/3 in the anterior cingulate cortex and in the restrosplenial cortex.

The Ciliopathy Gene Controls Mouse Forebrain Patterning via Region-Specific Modulation of Hedgehog/Gli Signaling. Primary cilia are essential for CNS development. In the mouse, they play a critical role in patterning the spinal cord and telencephalon via the regulation of Hedgehog/Gli signaling. However, despite the frequent disruption of this signaling pathway in human forebrain malformations, the role of primary cilia in forebrain morphogenesis has been little investigated outside the telencephalon. Here we studied development of the diencephalon, hypothalamus and eyes in mutant mice in which the ciliopathy gene is disrupted. At the end of gestation, fetuses displayed anophthalmia, a reduction of the ventral hypothalamus and a disorganization of diencephalic nuclei and axonal tracts. In embryos, we found that the ventral forebrain structures and the rostral thalamus were missing. Optic vesicles formed but lacked the optic cups. In embryos, () expression was virtually lost in the ventral forebrain but maintained in the zona limitans intrathalamica (ZLI), the mid-diencephalic organizer. Gli activity was severely downregulated but not lost in the ventral forebrain and in regions adjacent to the - expressing ZLI. Reintroduction of the repressor form of Gli3 into the background restored optic cup formation. Our data thus uncover a complex role of cilia in development of the diencephalon, hypothalamus and eyes via the region-specific control of the ratio of activator and repressor forms of the Gli transcription factors. They call for a closer examination of forebrain defects in severe ciliopathies and for a search for ciliopathy genes as modifiers in other human conditions with forebrain defects. The Hedgehog (Hh) signaling pathway is essential for proper forebrain development as illustrated by a human condition called holoprosencephaly. The Hh pathway relies on primary cilia, cellular organelles that receive and transduce extracellular signals and whose dysfunctions lead to rare inherited diseases called ciliopathies. To date, the role of cilia in the forebrain has been poorly studied outside the telencephalon. In this paper we study the role of the ciliopathy gene in mouse forebrain development. We uncover complex functions of primary cilia in forebrain morphogenesis through region-specific modulation of the Hh pathway. Our data call for further examination of forebrain defects in ciliopathies and for a search for ciliopathy genes as modifiers in human conditions affecting forebrain development.

DEVELOPMENTAL CHANGES OF NETWORK ACTIVITY IN THE SOMATOSENSORY CORTEX IN THE GLUTAMIC ACID DECARBOXYLASE 67 (GAD67)-GFP MOUSE MODEL.

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Timo Ueberbach[1], Thomas Mittmann[2]
[1]Universitätsmedizin Mainz, Institut Für Physiologie, Mainz, Germany, [2]University Medical Center of the Johannes Gutenberg-University, Institute Of Physiology, Mainz, Germany

Activation of ionotropic and metabotropic GABA-receptors and the subsequent neuronal hyperpolarization plays an important role to stabilize the level of excitation in the developing and adult brain. Here we used a transgenic mouse line expressing the Green Fluorescent Protein (GFP) under the control of the glutamic acid decarboxylase 67 (GAD67) promotor (Tamamaki et al., 2003), which is known to cause impaired GABA synthesis. Our aim was to investigate its impact on cortical network activity during development. We performed electrophysiological multi-electrode array (MEA) and whole-cell patch-clamp recordings in slices of the somatosensory cortex in vitro from GAD67-GFP mice at P8/9, P14/15 and P21/22. Our main results are a decreased spontaneous activity measured by cortical MEA recordings in normal ACSF in P8/9 and P14/15, but not in P21/22 animals as compared to WT-littermate animals. Whole-cell patch clamp recordings from layers II/III pyramidal neurons revealed a decreased frequency, but not amplitude of sIPSCs in GAD67-GFP mice at P14/15. Furthermore, the frequency and amplitude of mIPSCs was decreased in GAD67-GFP mice. Interestingly, the frequency of sEPSCs was also reduced indicating a potentially compensatory downregulation of the glutamatergic transmission. However, amplitude and frequency of evoked eEPSCs was not different compared to WT-mice. These data indicate that the impaired synthesis of GABA in our present GAD67-GFP mouse model does not automatically lead to a hyperexcitable cortical network during development, but it rather triggers homeostatic synaptic processes to keep the excitatory-to-inhibitory ratio balanced. This work was supported by a grant to TM (DFG, CRC 1080, C02).

The cerebral cortex has a complex yet exquisite network of neuronal circuits which is important for advanced brain functional and cognitive purposes. To explore the molecular mechanisms of neuronal circuit formation, the tactile somatosensory pathway that connects the whiskers and cortex of rodents is useful. The rodent somatosensory barrel cortex layer 4 (L4) comprises a unique 'barrel map' that corresponds to facial whisker patterns. The whisker inputs via the thalamus form the neuronal circuit in the barrel cortex L4 during early postnatal development. Thalamocortical (TC) axon terminals are clustered in the barrels, ring-shaped distributions of neurons in the barrel cortex L4. Dendrites of L4 neurons are oriented toward the barrel centre and receive inputs from the TC axon terminals. These traits make the barrel cortex a useful system to study neuronal circuit development. Our focus is Ras-GTPase activating protein (Ras-GAP) which possibly plays a role in the MAPK and PI-3 kinase pathways. We have created knockdown constructs for Ras-GAPs (NF1 and SynGAP) following which we transfected the constructs to the barrel cortex L4 using in-utero electroporation. We have analysed the effects of Ras-GAPs knockdown in the L4 circuit formation by the histological method. Our results suggest that Ras-GAPs knockdown L4 neurons may show reduced dendritic orientation. We also checked the colocalization of the post-synaptic L4 neuron dendritic spines and pre-synaptic TC axon terminals by confocal imaging. In the meeting, we would like to discuss the possible mechanisms for Ras-GAP-dependent L4 circuit formation.

THE EMERGENCE OF CORRELATED ACTIVITY IN THE DEVELOPING CORTEX IN VIVO

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Sofia Zangila, Ludovic Brivady, Jean Claude Platel, Rosa Cossart
Inserm-Aix-Marseille University, Inmed, Marseille, France

Neuronal activity plays a critical role in the developing brain, sculpting cortical circuits and orchestrating somatosensory map formation. During development, neurons undergo successive changes in their activity patterns, which evolve from asynchronous low-frequency single-cell firing in embryonic stages, to correlated activation after birth. In vitro experiments have shown that these early correlated activities, are initially mediated via electrical-synapses and sequentially by chemical-synapses. Interestingly, these major activity changes occur in the rodent brain during a narrow critical time window in the first postnatal week. Thus, our objective is to determine in vivo the cellular and activity-dependent mechanisms underlying network formation during the first postnatal week. In order to investigate when and how different correlated activity patterns emerge and change in space and time we used in vivo two-photon calcium imaging of multineuron dynamics in un-anesthetized mouse pups from birth onwards. We focus on the differential contribution of GABAergic interneurons and glutamatergic cells to such collective early dynamics. We uncover primary forms of correlated activity and show how the developmental timelines of local GABAergic and glutamatergic neurons do not converge until the end of the first postnatal week.

RULES GOVERNING THE DENDRITIC GROWTH OF MOTION-SENSING NEURONS IN DROSOPHILA

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Aicha Haji Ali, Nikolai Hoermann, Nikolas Drummond, Jesus Pujol-Marti, Alexander Borst

During development, neurons grow their dendrites to occupy a specific area to form synapses with their presynaptic partners. This is particularly clear in the case of T4 neurons, the first directionally tuned neurons of the ON pathway in *Drosophila* visual motion detection circuit. T4 neurons are divided into four subtypes, each tuned to motion in one of the four cardinal directions. This functional specificity of T4 neurons is strongly linked to the polarized orientation of their dendrites. Neurons of each subtype have their dendrites oriented primarily opposite to their preferred direction of motion (Takemura et al., 2013). All T4 subtypes connect to the same set of functionally distinct input neurons, but in a subtype-specific spatial order. It is the orientation of their dendrites that determines the correct sampling of inputs in visual space (Shinomiya et al., 2019). Therefore, growing the dendrite in the right orientation is essential for T4 function. We want to understand how T4 neurons manage to grow their dendrites to obtain the proper dendritic orientation corresponding to their subtypes. To understand more about this process and the cues that T4 dendrites read to guide their growth, we use two-photon time-lapse imaging of developing T4 neurons in an ex-vivo brain preparation. The image processing pipeline includes denoising and motion-removal to arrive at a pixel-based description of the area the dendrite covers at each time point during development.

The adult hippocampus serves multiple cognitive functions that rely on a complex neuronal network able to integrate multiple external inputs onto internally-generated dynamics. One way to better understand the morpho-functional connectome of the adult hippocampus is to analyze how the circuit assembles during development. We have shown that the second postnatal week in the developing mouse marks an abrupt switch in the representation of self-motion in local CA1 dynamics with a transient inhibition in response to motor twitches (Dard et al., 2022). At the same time, we observed the abrupt anatomical and functional emergence of a perisomatic GABAergic coverage in the stratum pyramidale. The beginning of the second postnatal week in the mouse roughly corresponds to the end of the third trimester of pregnancy in humans and of the second trimester in macaques (www.translatingtime.org; Clancy et al., 2007, doi:10.1385/NI:5:1:1). Here we use immunocytochemical labelling directed against different markers of GABAergic afferents such as GAD65, VGAT, synaptotagmin2, parvalbumin, to map the maturation of such perisomatic GABAergic innervation in the hippocampus of humans and non-human primates.

ACTIVITY-DEPENDENT MODULATION OF PGC1α REGULATES THE MATURATION OF CORTICAL PARVALBUMIN INTERNEURONS

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Monika Moissidis[1,2], Laura Modol-Vidal[1,2], Oscar Marín[1,2]
[1]King's College London, Centre For Developmental Neurobiology, London, United Kingdom, [2]King's College London, Mrc Centre For Neurodevelopmental Disorders, London, United Kingdom

Parvalbumin-expressing (PV) interneurons represent the most abundant subclass of cortical interneurons and are essential for the gating of excitatory cells activity. The transcriptional co-activator PGC1α, encoded by the *Ppargc1a* gene (Peroxisome proliferator activated receptor-gamma co-activator 1-alpha), is a master regulator of mitochondrial biogenesis and has been suggested to be important for the proper functioning of PV interneurons. However, the precise pattern of expression of *Ppargc1a* and its role in the maturation of PV interneurons during development are yet to be established. Here, we investigate whether the maturation of cortical PV interneurons is controlled by the activity-dependent modulation of *Ppargc1a* expression levels. We observed that *Ppargc1a* is expressed in selected classes of cortical interneurons during the early postnatal development of the mouse. This includes prospective PV interneurons, in which *Ppargc1a* is enriched before the onset of their terminal differentiation. PGC1α is required for the expression of a PV-specific genetic programme that is altered upon conditional deletion of *Ppargc1a* in interneurons derived from the medial ganglionic eminence. By interfering with the formation of excitatory synapses contacting PV interneurons, we found that *Ppargc1a* expression during development depends on the excitatory inputs received by these cells. Finally, using chemogenetic tools, we also uncover a mechanism by which abnormal network hyperactivation inhibits *Ppargc1a* expression and PV interneuron maturation. Overall, our results suggest that PGC1α functions as a cell-intrinsic molecular hub translating extrinsic cues into transcriptional programmes promoting the maturation of PV interneurons.

Early emergence of cortical interneuron diversity in the mouse embryo.
GABAergic interneurons (GABA, γ-aminobutyric acid) regulate neural-circuit activity in the mammalian cerebral cortex. These cortical interneurons are structurally and functionally diverse. Here, we use single-cell transcriptomics to study the origins of this diversity in the mouse. We identify distinct types of progenitor cells and newborn neurons in the ganglionic eminences, the embryonic proliferative regions that give rise to cortical interneurons. These embryonic precursors show temporally and spatially restricted transcriptional patterns that lead to different classes of interneurons in the adult cerebral cortex. Our findings suggest that shortly after the interneurons become postmitotic, their diversity is already patent in their diverse transcriptional programs, which subsequently guide further differentiation in the developing cortex.

Cortical pyramidal cells and GABAergic interneurons undergo extensive programmed cell death during early postnatal development in the mouse. However, the requirement of programmed cell death for the normal functioning of the cerebral cortex remains to be elucidated. Here we aim to understand how disruption of the normal neuronal composition of the cerebral cortex affects behaviour in mice. Specifically, we studied how changes in the number of pyramidal cells and interneurons in the cerebral cortex may impact cortical function in mice. To this end, we tested mice in which the programmed cell death of pyramidal cells is genetically abolished ($Nex^{Cre/+};Bak^{-/-};Bax^{fl/fl}$) using visual and tactile go/no-go discrimination tasks. We observed no significant differences in the performance of control and mutant mice on neither the visual nor the tactile discrimination task. However, while the training of control mice on the tactile discrimination task improves their ability to subsequently learn the visual discrimination, this transfer of knowledge does not occur in the mutant mice. Our results suggest that artificially increasing the number of pyramidal cells and GABAergic interneurons in the cerebral cortex of mice does not seem to have a significant effect on visual and tactile sensory processing, but it impacts complex cognitive functions like transfer of knowledge. Further experiments are needed to understand how changes in the final number of cortical neurons affect cortical networks and how that might result in the behavioural phenotypes described in this study.

Prenatal infections have been associated with increased risk of developing neuropsychiatric disorders. Animal models are powerful tools for studying how maternal immune activation during pregnancy can alter brain development in the offspring. In particular, rodents whose mother received a pro-inflammatory agent [Poly(I:C)] during gestation show alterations in dopaminergic (DA) circuits reminiscent of schizophrenia-associated phenotypes. How a prenatal immune challenge induces long-lasting alterations of DA signaling is poorly understood. We set out to study the mechanisms by which maternal immune activation causes long-term changes in DA neurons in the ventral tegmental area (VTA). Maternal immune activation was induced by Poly(I:C) administration in pregnant mice at embryonic stage E8.5. Juxta-cellular recordings in the VTA *in vivo* showed decreased neuronal activity of DA neurons in the offspring of Poly(I:C)-treated mice. Using patch-clamp recordings *ex vivo*, we found that VTA DA neurons from Poly(I:C) mice displayed an enhanced voltage sag in response to hyperpolarizing current injections and increased Ih currents, indicating higher expression and/or activity of HCN channels. However, neither the intrinsic firing properties nor the resting membrane potential were altered in Poly(I:C) mice, suggesting that changes in Ih have modest effects on neuronal activity. Next, we studied functional synaptic inputs to DA VTA DA neurons. We observed that the frequency of miniature excitatory, but not inhibitory postsynaptic currents, was strongly diminished in Poly(I:C) mice, indicating impaired excitatory/inhibitory balance in VTA DA neurons. Together, these results suggest that maternal immune activation may reduce VTA DA neuron activity through decreased excitatory synaptic inputs.

STRIKINGLY DIFFERENT NEUROTRANSMITTER RELEASE STRATEGIES AMONGST INTERNEURON SUBTYPES OF THE OLFACTORY BULB

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Ana Dorrego-Rivas, Darren Byrne, Yunyi Liu, Menghon Cheah, Matthew Grubb
King's College London, Centre For Developmental Neurobiology, London, United Kingdom

Neurons establish morphological polarity by specifying two different compartments: the axon and the somatodendritic domain. This polarity is also functional, because in most neurons dendrites receive the majority of inputs while axons generate output signals via neurotransmitter release. However, many exceptions to this dogma occur in the olfactory bulb (OB), where most GABAergic interneurons are anaxonic and can only release neurotransmitters from their dendrites. OB glutamatergic cells, however, have classic morphological polarity but release neurotransmitters from both axonal and somatodendritic domains. Dendritic release is, therefore, a common feature of OB neurons. A subset of GABAergic interneurons in the OB also release dopamine. These dopaminergic (DA) cells comprise two groups – axonic and anaxonic – depending on the presence or absence of an axon. Here, we provide structural and functional evidence showing that, unlike their anaxonic counterparts, axon-bearing DA neurons rarely if ever release GABA from their dendrites. We injected a Cre-dependent AAV in embryonic VGAT-Cre mice to obtain sparse cell morphology (GFP) plus structural evidence for putative neurotransmitter release sites (synaptophysin-mRuby), finding dendritic mRuby puncta almost exclusively in anaxonic cells. We then obtained electrophysiological recordings in acute slices from DAT-tdT mice, using an auto-evoked inhibition (AEI) protocol to detect dendritic GABA release. All anaxonic neurons displayed an AEI response, while almost all axonic DA cells did not. Our results suggest that axon-bearing DA neurons are the only OB cell type to *not* effect dendritic neurotransmitter release, placing a key spatial constraint on their ability to shape olfactory sensory processing.

Development of the mammalian main olfactory bulb.
The mammalian main olfactory bulb is a crucial processing centre for the sense of smell. The olfactory bulb forms early during development and is functional from birth. However, the olfactory system continues to mature and change throughout life as a target of constitutive adult neurogenesis. Our Review synthesises current knowledge of prenatal, postnatal and adult olfactory bulb development, focusing on the maturation, morphology, functions and interactions of its diverse constituent glutamatergic and GABAergic cell types. We highlight not only the great advances in the understanding of olfactory bulb development made in recent years, but also the gaps in our present knowledge that most urgently require addressing.

PERSISTENCE OF CAJAL-RETZIUS CELLS IN THE HIPPOCAMPUS IS REQUIRED FOR THE DEVELOPMENT OF DENDRITIC SPINES OF CA1 PYRAMIDAL CELLS

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Ingvild Glærum[1], Keagan Dunville[1], Nicola Montaldo[2], Maximiliano Nigro[1], Pål Sætrom[2], Barbara Van Loon[2], Giulia Quattrocolo[1]
[1]NTNU, Kavli Institute For Systems Neuroscience, Trondheim, Norway, [2]NTNU, Department Of Clinical And Molecular Medicine, Trondheim, Norway

The hippocampus is a brain structure acknowledged for its role in memory formation, learning and the representation of space. To facilitate this, the hippocampus is comprised of a diverse set of neurons, including Reln$^+$ glutamatergic Cajal-Retzius neurons (CR). Although neocortical CR-cells disappear soon after birth, hippocampal CR-cells persist for an extended period during postnatal development. CR-cells are actively integrated in the hippocampal microcircuit, though their influence on postnatal development is poorly understood. To address this, we injected a Cre-dependent AAV virus expressing diphtheria toxin fragment A in a Pde1c-Cre mouse line at postnatal day 0 (P0) to selectively ablate CR-cells. With this approach, ~90% of hippocampal CR-cells are ablated by P15 and sustained throughout the experimental endpoint at P30. This method enables us to investigate hippocampal development and function when CR-cells are prematurely removed. In vitro electrophysiological experiments show that CR-cell ablation affects the connectivity of CA1 pyramidal cells. Analysis of dendritic spines highlighted significant differences both in density and the type of spines present on CA1 pyramidal cells, in all hippocampal layers, suggesting that removal of CR-cells skews the trajectory of spine development of CA1 pyramidal cells. Thereafter, we performed bulk RNA sequencing from dorsal hippocampus at P15 and P30 to assess underlying genetic mechanisms that CR-cell ablation alters. Synaptic gene ontology analysis show that CR-cell ablation led to negative enrichment of synaptic function and cellular components. Our data suggests that the persistence of CR-cells in the postnatal hippocampus is critical for proper maturation of the hippocampal circuit.

PRO- AND MATURE-BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) CONTROL NEURONAL CHLORIDE HOMEOSTASIS THROUGH CATION-CHLORIDE CO-TRANSPORTER ACTIVITY KCC2

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Mira Hamze[1,2,3], Igor Medina[1,2,3], Christophe Porcher[1,2,3]
[1]Aix-Marseille-Université, Inserm Inmed, MARSEILLE, France, [2]INSERM (Institut National de la Santé et de la Recherche Médicale), Umr1249, MARSEILLE, France, [3]INMED (Institut de Neurobiologie de la Méditerranée), Inserm, MARSEILLE, France

The strength of GABAergic inhibitory transmission is dependent on intracellular neuronal chloride concentration ([Cl-]i), mainly regulated by activity of the cation-chloride co-transporter KCC2. Among many molecules controlling its function and affecting neuronal [Cl-]i is brain-derived neurotrophic factor (BDNF). BDNF is synthesized from precursor proteins (proBNDF) that are cleaved to yield to mature BDNF (mBDNF). mBDNF interacts with the TrkB receptor to activate set of TrkB-dependent signaling cascades, whereas proBDNF interacts with the $p75^{NTR}$ to affect distinct cellular responses. Although previous studies showed the implication of BDNF signaling in KCC2 functional activity, the involved cellular mechanisms remain unclear. Here, we investigated the interplay between both forms of BDNF and chloride homeostasis in primary cultures of rat hippocampal neurons using gramicidin perforated-patch recordings, live-cell immunolabeling of KCC2 and NH4(+)-induced pHi shifts. We found that in mBDNF expressing neurons, the value of the reversal potential of GABA responses (EGABA) is more negative in immature neurons, whereas in proBDNF expressing neurons, EGABA is more positive in mature neurons. Analysis of cell surface expression of KCC2 confirms the electrophysiological data showing a KCC2 up-regulation and downregulation in mBDNF and proBDNF expressing neurons respectively. At last, in immature neurons, both forms of BDNF showed a significant increase in KCC2 activity, whereas in mature neurons, pro- and mBDNF modify KCC2 activity in opposite direction. Finally, our findings highlight the significant potential role of BDNF signaling for regulating chloride transport through the control of KCC2 activity and thereby to fine-tune the strength of inhibitory synaptic transmission.

RAPID PRESYNAPTIC MATURATION IN NATURALLY REGENERATING AXONS

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Lorcan Browne, Andres Crespo, Matthew Grubb
King's College London, Centre For Developmental Neurobiology, London, United Kingdom

Studying naturally occurring processes of neuronal regeneration has the potential to inform therapeutic attempts at brain repair. Here we examined presynaptic maturation in the regenerating adult mammalian olfactory system, where damaged neurons can naturally re-grow axons to re-establish functional connections with target circuitry. After inducing olfactory sensory neuron (OSN) degeneration with a single dose of the olfactotoxin methimazole (MMZ), we characterised the resultant degeneration and subsequent functional reconnection of OSN axon terminals with their postsynaptic targets in the olfactory bulb (OB). Morphologically, OSN axon terminals degenerated for ~10-15 days post-MMZ injection (DPI), followed by a slower regeneration phase from ~15-45 DPI. Functionally, electrophysiological recordings in acute OB slices revealed a much more rapid increase in OSN-to-OB connectivity that began at 13 DPI and reached control levels just a few days later. Re-connecting axon terminals, whilst capable of robust neurotransmission at these early stages, displayed significantly weaker paired-pulse depression, indicating that their release probability may be lower compared to mature connections. This effect was only present in the most immature synapses, returning rapidly to control levels by 22-30 DPI, and could not be explained by differences in either AMPA receptor desensitisation or presynaptic inhibition. Newly arriving axons also display fully mature levels of presynaptic inhibition in response to dopaminergic D_2 and GABAergic $GABA_B$ agonists. Our data suggest that naturally regenerating axon terminals in the adult mammalian brain are almost fully mature when they reach their postsynaptic targets, but undergo a brief phase of functional maturation after they first re-establish synaptic connectivity.

INSULIN REGULATES GABAERGIC NEUROTRANSMISSION IN HIPPOCAMPAL NEURONS IN WILD-TYPE MICE AND A MOUSE MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Hayma Hammoud[1], Olga Netsyk[1], Atieh Tafreshiha[1], Sergiy Korol[1], Zhe Jin[1], Jin-Ping Li[2], Bryndis Birnir[1]

Aims To investigate the effect of insulin on γ-aminobutyric acid (GABA)-activated currents in hippocampal neurons in Alzheimer's disease (AD) model tg-APPSwe mice in comparison with wild-type mice. **Methods** Whole-cell patch-clamp assay was performed to record GABA-activated currents in hippocampal neurons (dentate gyrus granule cells and CA3 pyramidal cells) of acute brain slices, from wild-type and tg-APPSwe mice at different ages, in the presence or absence of insulin. **Results** In wild-type mice (8-10 weeks old), insulin (1nM) increased the total spontaneous inhibitory postsynaptic current (sIPSC) density in dentate gyrus granule cells from both dorsal and ventral hippocampus, and the extrasynaptic current density in dorsal CA3 pyramidal cells. In addition, insulin increased miniature IPSC (mIPSC) frequency in dentate gyrus granule cells and dorsal CA3 pyramidal cells. In 5-6 months old wild-type and tg-APPSwe mice, insulin modulated neither the total sIPSC density nor extrasynaptic current density. In dentate gyrus granule cells from 5-6 months old tg-APPSwe mice, the total sIPSC density was significantly reduced as compared to wild-type mice and increased by insulin treatment. In contrast, the extrasynaptic current density was increased in tg-APPSwe mice (5-6 and 10-12 months old) as compared with wild-type littermates, but only reduced by insulin in 10-12 months old tg-APPSwe mice. **Conclusions** Insulin differentially modulates GABA-activated neurotransmission in the hippocampus, which depends on neuronal type, subtype of neuronal inhibition, age and disease model. GABAB RECEPTOR-MEDIATED EFFECTS IN VIP-EXPRESSING INTERNEURONS OF THE DENTATE GYRUS

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Zhengzheng He[1], Yoshihisa Ishihara[2], Cheng-Chang Lien[3], Imre Vida[1]
[1]Charité-Universitätsmedizin Berlin, Institute Of Integrative Neuroanatomy, Berlin, Germany, [2]Toho University, Department Of Anatomy, Tokyo, Japan, [3]National Yang Ming Chiao Tung University, Institute Of Neuroscience And Brain Research Center, Taipei, Taiwan

The dentate gyrus (DG) acts as a gateway to the hippocampus, processing multi-modal information arriving from neocortical areas via the entorhinal cortex. In its netwotk, principal neurons, the granule cells, interact with a morphologically, physiologically, and neurochemically hetergogenous population of inhibitory GABAergic interneurons (INs). Among various IN types, vasoactive intestinal peptide-expressing (VIP) INs are known to selectively target other INs and thereby directly modulate the GABAergic system. GABA acts in addition to ionotropic $GABA_A$ via metabotropic $GABA_B$ receptors. $GABA_B$ receptors mediate diverse effects in cortical networks and are particularly highly expressed in INs, however their action in VIP-INs has not been studied. Therefore. to elucidate the function of $GABA_B$ receptors ($GABA_B$Rs) in the regulation of the electrical activity of DG VIP-INs, the effects of $GABA_B$R agonist and antagonist on VIP-INs were investigated in VIP/tdTomato mouse slices by whole-cell patch-clamp recordings. The result revealed that VIP-INs have small round somata (5-15 µm) located in all subregions of the DG and with distinct axonal projection patterns, and display various input resistances as well as different discharge patterns, as reported recently (Wei et a., 2021). Bath application of the agonist baclofen (10 µM) induced a hyperpolarization and reduced excitability of VIP-INs. This effect was underlied by an outward whole-cell current of 40 ± 10.2 pA in DG VIP-INs which was fully reversed by the application of the antagonist CGP (5 µM). These results suggest that postsynaptic $GABA_B$Rs are highly expressed and modulate the activity of VIP-INs of the DG.

Neuronal networks consist of multiple types of neurons with distinct roles. Extracellular techniques allow monitoring activity at a single spike/single neuron spatiotemporal resolution. Optogenetic stimulation can tag one or two cell types per animal. However, there is no way to determine the type of a recorded neuron in vivo, without optical stimulation or visualization. Here, we generated a ground-truth dataset for classifying four different types of neurons in mouse neocortex and hippocampus. We collected optically-tagged spike data from 19 freely-moving transgenic mice. Every mouse expressed ChR2 under a different promoter: Calcium/calmodulin-dependent kinase (CaMKII), parvalbumin (PV), somatostatin (SOM), or cholecystokinin (CCK). Because some excitatory cells express CCK, we specifically targeted inhibitory CCK cells by viral vector injection into mice transgenic for both CCK and vesicular GABA transporter. From each animal, extracellular data were recorded over several months using high-density silicon probes coupled with optical fibers. Since illumination of excitatory CaMKII cells activates non-CaMKII cells indirectly with millisecond-timescale latency, we identified directly-activated CaMKII cells by white-noise stimulation. For every optically-tagged neuron, we derived a feature set based on spike waveforms, timing, and the propagation of extracellular voltage in space. The four-cell type dataset provides a unique ground-truth basis for training new classifiers. A cross validated classifier trained on this dataset will enable cell type identification in non-optical animals, facilitating more precise interpretation of extracellular recordings and deeper understanding of network dynamics.

ROLE OF THE PRESYNAPTIC SV2A PROTEIN IN THE CONTROL OF EXCITATION/INHIBITION (E/I) BALANCE IN HIPPOCAMPAL CA3 CIRCUITS

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Julio Viotti, Mathilde Guibourd-De-Luzinais, Noelle Grosjean, Severine Deforges, Eva Rodrigues, Christophe Mulle
CNRS/Université de Bordeaux, Institute For Interdisciplinary Neuroscience (iins) - Umr 5297, Bordeaux, France

The presynaptic vesicle protein SV2A is the binding site for the antiepileptic drug levetiracetam, and a widely used tomography synaptic marker. However, the function of SV2A, ubiquitously expressed in the brain, has remained rather elusive. Constitutive SV2A knock-out mice display severe seizures and death after a few weeks, and mutation of the protein in humans can lead to epilepsy. We have examined the electrophysiological consequences of deleting SV2A from either excitatory or inhibitory input onto CA3 pyramidal cells. For this, we have used SV2A-conditional KO mouse in combination with viral gene transfer to allow for expression of the Cre recombinase and an optogenetic tool (ChIEF) in either dentate gyrus granule cells or CA3 interneurons. Removing SV2A from dentate gyrus granule cells led to a decreased E/I ratio during burst activity and this effect was due to an increase in feed-forward inhibition onto the pyramidal cells. Surprisingly, when inhibition was pharmacologically blocked, excitatory mossy fiber to CA3 pyramidal cell responses during high frequency stimulation were also increased. We also show that the absence of SV2A in CA3 interneurons does not affect synaptic transmission onto pyramidal cells. Overall, we show how the absence of SV2A leads to an increased of inhibition of CA3 pyramidal cells, not by directly affecting inhibitory transmission but by increasing excitation of interneurons, intensifying feed-forward inhibition from DG to CA3.

THE ROLE OF AXOAXONIC CELLS IN CONTROLLING PREFRONTAL FIRING ACTIVITY IN VIVO

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Cloé Lheraux[1,2], Juliette Vivien[3], Cyril Herry[3], Thomas Bienvenu[3,4,5]
[1]Neuroscience, Université De Bordeaux, Bordeaux cedex, France, [2]INSERM U1215, Neurocentre Magendie, Bordeaux, France, [3]Inserm U1215, Neurocentre Magendie, Bordeaux, France, [4]Charles Perrens, Centre Hospitalier, Bordeaux, France, [5]Neuroscience, Université De Bordeaux, Bordeaux Cedex, France

Axoaxonic Cells (AAC) are among the most intriguing GABAergic interneurons of the cerebral cortex. Synapsing with the axon initial segment (AIS) of pyramidal neurons (PN), where action potentials are initiated, they are thought to play a critical role in the modulation of cortical network activities. However, how AAC regulate PN firing activity remains uncertain. *In vitro* studies showed AAC's activation to display both excitatory and inhibitory effects on PN (Szabadics et al., 2006; Glickfeld et al., 2009; Woodruff et al., 2011; Pan-Vazquez et al., 2020). A recent *in vivo* study found an inhibition of 14.9% of PN after AAC optogenetic simulation in the CA1 region of the hippocampus (Dudok et al., 2021). Additionally, in the neocortex, a predominant inhibitory effect of AAC activation was reported (Lu et al., 2017). However, information on the net effect of AAC on neocortical PN is still incomplete and debated. Thus, in this project we leveraged the development of a transgenic mouse line that selectively targets AAC *in vivo,* with inducible Nkx2.1-dependent reporters (He et al., 2016; Taniguchi et al., 2013); and combine large-scale electrophysiological recordings of dorsomedial prefrontal PN with optogenetic activation of AAC *in vivo* in drug-free mice. With this approach, we provide evidence for the net effect of AAC activation on PN's firing in the neocortex. This work provides a better understanding of the regulation of cortical motifs by AAC, which might be altered in neuropsychiatric disorders.

DENTATE GYRUS INHIBITORY MICROCIRCUIT PROMOTES NETWORK MECHANISMS UNDERLYING MEMORY CONSOLIDATION

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Hannah Twarkowski[1,2,3], Victor Steininger[1,2,3,4], Min Jae Kim[1,2,3,5], Amar Sahay[1,2,3,6]
[1]Massachusetts General Hospital, Center For Regenerative Medicine, Boston, United States of America, [2]Harvard University, Harvard Stem Cell Institute, Cambridge, United States of America, [3]Harvard Medical School, Department Of Psychiatry, Boston, United States of America, [4]Ecole Polytéchnique Fédérale de Lausanne, Brain Mind Institute, Lausanne, Switzerland, [5]John Hopkins University, Department Of Biomedical Engineering, Baltimore, United States of America, [6]Broad Institute of Harvard and Massachusetts Institute of Technology, Broad Institute, Cambridge, United States of America

The dentate gyrus (DG) to CA3 pathway plays a key role in encoding experiences that are ultimately consolidated in the anterior cingulate cortex (ACC). Experience-dependent changes among excitatory neurons in the DG-CA3 circuit have been intensely studied. However, DG cells innervate not only CA3 pyramidal neurons but also inhibitory, parvalbumin-positive interneurons to provide strong feed-forward inhibition (FFI) onto CA3 pyramidal neurons. Following learning, FFI onto CA3 is temporarily increased which may be a key element for consolidation and long-term memory storage in hippocampal-cortical networks. The underlying mechanisms through which this inhibitory microcircuit mediates memory consolidation in hippocampal-cortical networks are not well understood. We harnessed a molecular tool to investigate how increased FFI in this microcircuit affects downstream neuronal ensembles and network oscillations during memory consolidation. We performed longitudinal *in vivo* calcium imaging in CA1 and ACC during contextual fear learning in mice with virally enhanced FFI in the DG-CA3 circuit. We found that selectively increasing FFI facilitated formation and maintenance of neuronal representation in both brain regions as it prevented a time-dependent decay of neuronal representations. Furthermore, the specificity of neuronal representation was increased in a time-dependent manner in ACC. Simultaneous recordings of local field potentials (LFPs) in CA1 and ACC revealed that virally enhanced FFI increased coupling of sharp-wave ripples and spindles, a mechanism for hippocampal-cortical communication during memory consolidation. This study links a defined synaptic mechanism in a DG-CA3 inhibitory microcircuit with ensemble dynamics and network oscillations and provides direct evidence for its role in memory consolidation.

NRG1 HAPLOINSUFFICIENCY ALTERS THE HOMEOSTASIS OF INHIBITORY CORTICAL CIRCUITS

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Yaiza Domínguez Canterla[1], Carmen Navarro-González[1], Héctor Carceller[1], Marina Benito Vicente[2], Irene Serra[3], Marta Navarrete[3], Angela Rodriguez-Prieto[1], Ana González Manteiga[1], Pietro Fazzari[1]

Neuregulin 1 (Nrg1) is a major schizophrenia (SZ) risk gene that controls the development of neuronal circuits. Nrg1 polymorphisms linked to SZ locate mainly in non-coding regions and they may partially reduce Nrg1 expression. Most previous studies focused on the characterization of mouse models deficient for ErbB4, the receptor for both Nrg1 and Neuregulin 3. Here, we investigated the alterations of cortical circuits in a new mouse model of Nrg1 haploinsufficiency (Nrg1 tm1Lex). To this aim, we used multidisciplinary approaches as Magnetic Resonance Spectroscopy, electrophysiology, quantitative confocal imaging and molecular analysis. We observed changes in the expression of molecules involved in GABAergic neurotransmission, decreased density of Vglut1 excitatory buttons onto Parvalbumin interneurons and decreased frequency of spontaneous inhibitory postsynaptic currents. In the prefrontal cortex, we observed an imbalance of the inhibitory circuits and a decreased number of Parvalbumin interneurons. Conversely, we failed to observe major alterations in excitatory neurons that were previously reported in ErbB4 null mice. Altogether, our work suggests that Nrg1 haploinsufficiency alters the inhibitory circuits in the cortex and provides new insights into molecular synaptic impairment caused by Nrg1 in a preclinical model of SZ.

Nrg1 haploinsufficiency alters inhibitory cortical circuits.
Neuregulin 1 (NRG1) and its receptor ERBB4 are schizophrenia (SZ) risk genes that control the development of both excitatory and inhibitory cortical circuits. Most studies focused on the characterization ErbB4 deficient mice. However, ErbB4 deletion concurrently perturbs the signaling of Nrg1 and Neuregulin 3 (Nrg3), another ligand expressed in the cortex. In addition, NRG1 polymorphisms linked to SZ locate mainly in non-coding regions and they may partially reduce Nrg1 expression. Here, to study the relevance of Nrg1 partial loss-of-function in cortical circuits we characterized a recently developed haploinsufficient mouse model of Nrg1 (Nrg1). These mice display SZ-like behavioral deficits. The cellular and molecular underpinnings of the behavioral deficits in Nrg1 mice remain to be established. With multiple approaches including Magnetic Resonance Spectroscopy (MRS), electrophysiology, quantitative imaging and molecular analysis we found that Nrg1 haploinsufficiency impairs the inhibitory cortical circuits. We observed changes in the expression of molecules involved in GABAergic neurotransmission, decreased density of Vglut1 excitatory buttons onto Parvalbumin interneurons and decreased frequency of spontaneous inhibitory postsynaptic currents. Moreover, we found a decreased number of Parvalbumin positive interneurons in the cortex and altered expression of Calretinin. Interestingly, we failed to detect other alterations in excitatory neurons that were previously reported in ErbB4 null mice suggesting that the Nrg1 haploinsufficiency does not entirely phenocopies ErbB4 deletions. Altogether, this study suggests that Nrg1 haploinsufficiency primarily affects the cortical inhibitory circuits in the cortex and provides new insights into the structural and molecular synaptic impairment caused by NRG1 hypofunction in a preclinical model of SZ.

A Scalable Method to Study Neuronal Survival in Primary Neuronal Culture with Single-cell and Real-Time Resolution.
Neuronal loss is at the core of many neuropathologies, including stroke, Alzheimer's disease, and Parkinson's disease. Different methods were developed to study the process of neuronal survival upon cytotoxic stress. Most methods are based on biochemical approaches that do not allow single-cell resolution or involve complex and costly methodologies. Presented here is a versatile, inexpensive, and effective experimental paradigm to study neuronal survival. This method takes

advantage of sparse fluorescent labeling of the neurons followed by live imaging and automated quantification. To this aim, the neurons are electroporated to express fluorescent markers and co-cultured with non-electroporated neurons to easily regulate cell density and increase survival. Sparse labeling by electroporation allows a simple and robust automated quantification. In addition, fluorescent labeling can be combined with the co-expression of a gene of interest to study specific molecular pathways. Here, we present a model of stroke as a neurotoxic model, namely, the oxygen-glucose deprivation (OGD) assay, which was performed in an affordable and robust homemade hypoxic chamber. Finally, two different workflows are described using IN Cell Analyzer 2200 or the open-source ImageJ for image analysis for semi-automatic data processing. This workflow can be easily adapted to different experimental models of toxicity and scaled up for high-throughput screening. In conclusion, the described protocol provides an approachable, affordable, and effective in vitro model of neurotoxicity, which can be suitable for testing the roles of specific genes and pathways in live imaging and for high-throughput drug screening.

PKA ACTIVITY IN LAYER 2/3 OF SOMATOSENSORY CORTEX IN BEHAVING MICE

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Shinobu Nomura[1], Philipp Flotho[2], Bernd Kuhn[1]
[1]Okinawa Institute of Science and Technology, Optical Neuroimaging Unit, Okinawa, Japan, [2]Saarland University, Faculty Of Medicine, Homburg/Saar, Germany

Catecholamines influence animal behavior by controlling the excitability of neurons through G-protein coupled receptors and second messengers including cAMP/PKA signaling. However, little is known about the real-time cellular dynamics of endogenous catecholaminergic transmission in awake animals. Here, we imaged protein kinase A (PKA) activity in dendrites and somata of cortical layer 2/3 of awake mice with two photon microscopy and the single-chromophore PKA sensor GakdYmut with high temporal resolution (6.2Hz). For simultaneous PKA and Ca^{2+} imaging, we combined GakdYmut and the red Ca^{2+} sensor jR-GECO1a. When switching from isoflurane anesthesia (1%) to full wakefulness, the basal PKA activity increased by 22% and 12% in dendrites and somata, respectively (440 dendrites, 190 somata, 5 mice). During anesthesia and wakefulness, the PKA activity was suppressed by the β adrenoceptor agonist propranolol and D1 receptor antagonist sch23390. In contrast, α2 adrenoceptor antagonist yohimbine increased PKA activity. During wakefulness, we detected Ca^{2+} activity increase that synchronized with the locomotion of mice. However voluntary running induced typically biphasic PKA activity: decrease during locomotion followed by an overshooting rebound peaking about 25s after locomotion offset. Individual somata and dendrites showed a continuum of responses from only decrease during running to only increase after locomotion and changed their response type with every locomotion event. PKA activity was not correlated with Ca^{2+} activity in dendrites and somata. Yohimbine increased locomotion induced PKA activity. Our experiments show that α2 and β adrenoceptor set the basal PKA activity and voluntary locomotion causes PKA activity changes mediated by these adrenoceptors.

Aims: Chronic persistence of neonicotinoids raises concerns over its potential adverse effects in vertebrates. We investigated the effects of a thiacloprid on brain neuroplasticity, using zebrafish and mouse models. **Methods:** In the first experiment, we exposed zebrafish eleutheroembryo to 10^{-6} M to 10^{-8} M thiacloprid and collected whole heads 6 days postfertilization. In the second experiment, mice dams were exposed to 0.06, 0.6 and 6mg /kg/day to prenatal and 35-day old male and female offspring euthanized and cingular gyrus, hypothalamus, hippocampus and cerebellum isolated. In mice and zebrafish, markers of neuroplasticity and steroid action were quantified by RT-qPCR. **Results:** Here, thiacloprid did not affect any of the markers investigated in zebrafish eleutheroembryos. In mice amygdala, we observed a significant dose-dependent increase of doublecortin and PCNA and a reduction in aromatase transcription. In the hypothalamus, we found a dose-dependent decrease in ERbeta, nestin, synapsin IIA, synaptophysin neurogenin aromatase BDNF. PCNA was reduced at the lowest dose in the Cerebellum. Finally in the hippocampus, doublecortin, neurogenin, aromatase, nestin and synaptic markers were also reduced in a dose-dependent manner. We did not see any interaction with sex. **Conclusions:** Prenatal exposure to thiacloprid resulted in dose dependent alteration in the neuronal and steroid markers in specific brain areas only in mice, not in zebrafish. This could be due to the dose used or receptor specificity indicating the need for further investigations on the effects of neonicotinoids in the developing vertebrate brain.

Correlation of serum uric acid with heart rate variability in hypertension.
Autonomic dysfunction with dominant sympathetic tone is a common finding among hypertensives and prehypertensives. Uric acid is one of the independent predictors of hypertension. There are very few studies which have shown a relationship between the autonomic tone and uric acid generation pathway among prehypertensives and hypertensives. Aim of the study was to estimate and correlate serum uric acid levels with autonomic function as measured by heart rate variability (HRV) among prehypertensives and hypertensives.

Stress as a Cause of Recurrent Aphthous Stomatitis and Its Correlation with Salivary Stress Markers.
Stress causes an increase in cortisol and amylase. Recurrent aphthous stomatitis (RAS) results due to a multitude of causes, amongst which stress is one of the most important. Aim of the study was to estimate the level of stress, serum cortisol, salivary cortisol, amylase and electrolytes in subjects with RAS. 34 subjects with RAS (cases) were compared with 34 controls. Stress was measured using state trait anxiety inventory (STAI). Serum cortisol (Radioimmunoassay), Salivary cortisol, amylase (ELISA) and electrolytes (Flame photometry) were measured. Statistical analysis was done using SPSS 18.0 version software. The mean STAI scores were 48.71 ± 4.6 in cases and 46.74 ± 6.4 in controls (P = 0.13). The mean salivary cortisol concentration was 3.35 ± 1.8 ng/dl in cases and 3.65 ± 2.5 ng/dl in controls (P = 0.78). The mean salivary amylase was 155.09 ± 116.1 U/ml in cases and 128.74 ± 86.3 U/ml in controls (P = 0.49). The salivary sodium (0.24 ± 0.4 in both groups) and potassium (0.65 ± 0.5 in cases and 0.82 ± 0.4 in controls; P = 0.07) was not different in the two groups (electrolytes in mEq/dl). No correlation was seen between the salivary stress markers and STAI scores. Though stress was higher in RAS group none of the measured parameters were different from the control group. Stress may cause RAS but, in this study, there was no change in the salivary homeostasis.

EXPOSURE TO BLUE LIGHT AT NIGHT DURING ADOLESCENCE INDUCES NEUROTRANSMITTER PLASTICITY IN THE AMYGDALA AFFECTING EMOTIONAL RESPONSES IN MICE

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Alessandra Porcu, Sydney Goss, Brigitte Pulimootil, Davide Dulcis
University of California San Diego, Psychiatry, La Jolla, United States of America

Anxiety and mood disorders are the most common mental health problem in adolescents. Human studies showed that prolonged blue light exposure at night was associated with anxiety, lower self-control, and less social interactions in adolescents. **Aim:** The aim of this study is to test whether blue light affects amygdala neuroplasticity during adolescence regulating emotional responses to reveal whether prolonged blue light exposure represents an early risk factor for developing psychiatric disorders. **Methods:** We developed a new light paradigm to mimic human adolescent light exposure in mice: a prolonged light phase (19hrs/day) with light exposure during the night phase. Adolescent mice were exposed to either such light protocol or to control conditions (12hrs/day) for 4 weeks, then tested for anxiety-like behavior. Immunofluorescence, chemogenetic approach and fiber photometry were used to establish the effect of blue light on neurotransmitter plasticity in the amygdala and emotional responses. **Results:** Exposure to blue light protocol increased anxiety-like responses and induced a significance difference in the number of GABAergic and somatostatin neurons in the amygdala in adolescent mice. *In vivo* Ca^{2+} recording revealed increased somatostatin activity in the amygdala associated with impaired social behavior in adolescent mice exposed to blue light protocol. Chemogenetic inhibition of amygdala GABAergic neurons interfered with light-mediated neurotransmitter plasticity and reduced anxiety states in adolescent mice. **Conclusions:** Our data indicate that prolonged blue light exposure induces a form of neuroplasticity in the amygdalamediating anxiety and risky choice behaviors during adolescence, revealing new strategies to advance mental health in human adolescents.

Neurobiological and behavioral mechanisms of circadian rhythm disruption in bipolar disorder: A critical multi-disciplinary literature review and agenda for future research from the ISBD task force on chronobiology.
Symptoms of bipolar disorder (BD) include changes in mood, activity, energy, sleep, and appetite. Since many of these processes are regulated by circadian function, circadian rhythm disturbance has been examined as a biological feature underlying BD. The International Society for Bipolar Disorders Chronobiology Task Force (CTF) was commissioned to review evidence for neurobiological and behavioral mechanisms pertinent to BD.

COR758, a negative allosteric modulator of GABA receptors.
Allosteric modulators of G protein coupled receptors (GPCRs), including GABARs (GABARs), are promising therapeutic candidates. While several positive allosteric modulators (PAM) of GABARs have been characterized, only recently the first negative allosteric modulator (NAM) has been described. In the present study, we report the characterization of COR758, which acts as GABAR NAM in rat cortical membranes and CHO cells stably expressing GABARs (CHO-GABA). COR758 failed to displace the antagonist [H]CGP54626 from the orthosteric binding site of GABARs showing that it acts through an allosteric binding site. Docking studies revealed a possible new allosteric binding site for COR758 in the intrahelical pocket of the GABA monomer. COR758 inhibited basal and GABAR-stimulated O-(3-[Sthio)-triphosphate ([S]GTPγS) binding in brain membranes and blocked the enhancement of GABAR-stimulated [S]GTPγS binding by the PAM GS39783. Bioluminescent resonance energy transfer (BRET) measurements in CHO-GABA cells showed that COR758 inhibited G protein activation by GABA and altered GABAR subunit rearrangements. Additionally, the compound altered GABAR-mediated signaling such as baclofen-induced inhibition of cAMP production in transfected HEK293 cells, agonist-induced Ca mobilization as well as baclofen and the ago-PAM CGP7930 induced phosphorylation of extracellular signal-regulated kinases (ERK1/2) in CHO-

GABA cells. COR758 also prevented baclofen-induced outward currents recorded from rat dopamine neurons, substantiating its property as a NAM for GABARs. Altogether, these data indicate that COR758 inhibits G protein signaling by GABARs, likely by interacting with an allosteric binding-site. Therefore, COR758 might serve as a scaffold to develop additional NAMs for therapeutic intervention.

Vulnerability to helpless behavior is regulated by the circadian clock component CRYPTOCHROME in the mouse nucleus accumbens.
The nucleus accumbens (NAc), a central component of the midbrain dopamine reward circuit, exhibits disturbed circadian rhythms in the postmortem brains of depressed patients. We hypothesized that normal mood regulation requires proper circadian timing in the NAc, and that mood disorders are associated with dysfunctions of the NAc cellular circadian clock. In mice exhibiting stress-induced depression-like behavior (helplessness), we found altered circadian clock function and high nighttime expression of the core circadian clock component CRYPTOCHROME (CRY) in the NAc. In the NAc of helpless mice, we found that higher expression of CRY is associated with decreased activation of dopamine 1 receptor-expressing medium spiny neurons (D1R-MSNs). Furthermore, D1R-MSN-specific CRY-knockdown in the NAc reduced susceptibility to stress-induced helplessness and increased NAc neuronal activation at night. Finally, we show that CRY inhibits D1R-induced G protein activation, likely by interacting with the Gs protein. Altered circadian rhythms and CRY expression were also observed in human fibroblasts from major depressive disorder patients. Our data reveal a causal role for CRY in regulating the midbrain dopamine reward system, and provide a mechanistic link between the NAc circadian clock and vulnerability to depression.

Pharmacological Manipulation of the Circadian Clock: A Possible Approach to the Management of Bipolar Disorder.
Bipolar disorder (BD) is a mood disorder with genetic and neurobiological underpinnings, characterized primarily by recurrent episodes of mania and depression, with notable disruptions in rhythmic behaviors such as sleep, energy, appetite and attention. The chronobiological links to BD are further supported by the effectiveness of various treatment modalities such as bright light, circadian phase advance, and mood-stabilizing drugs such as lithium that have effects on the circadian clock. Over the past 30 years, the neurobiology of the circadian clock has been exquisitely described and there now exists a detailed knowledge of key signaling pathways, neurotransmitters and signaling mechanisms that regulate various dimensions of circadian clock function. With this new wealth of information, it is becoming increasingly plausible that new drugs for BD could be made by targeting molecular elements of the circadian clock. However, circadian rhythms are multidimensional and complex, involving unique, time-dependent factors that are not typically considered in drug development. We review the organization of the circadian clock in the central nervous system and briefly summarize data implicating the circadian clock in BD. We then consider some of the unique aspects of the circadian clock as a drug target in BD, discuss key methodological considerations and evaluate some of the candidate clock pathways and systems that could serve as potential targets for novel mood stabilizers. We expect this work will serve as a roadmap to facilitate the development of compounds acting on the circadian clock for the treatment of BD.

Acid Suspends the Circadian Clock in Hypoxia through Inhibition of mTOR.
Recent reports indicate that hypoxia influences the circadian clock through the transcriptional activities of hypoxia-inducible factors (HIFs) at clock genes. Unexpectedly, we uncover a profound disruption of the circadian clock and diurnal transcriptome when hypoxic cells are permitted to acidify to recapitulate the tumor microenvironment. Buffering against acidification or inhibiting lactic acid production fully rescues circadian oscillation. Acidification of several human and murine cell lines, as well as primary murine T cells, suppresses mechanistic target of rapamycin complex 1 (mTORC1) signaling, a key regulator of translation in response to metabolic status. We find that acid drives peripheral redistribution of normally perinuclear lysosomes away from perinuclear RHEB, thereby inhibiting the activity of lysosome-bound mTOR. Restoring mTORC1 signaling and the translation it governs rescues clock oscillation. Our findings thus reveal a model in which acid produced during the cellular metabolic response to hypoxia suppresses the circadian clock through diminished translation of clock constituents.

Photoperiod-Induced Neuroplasticity in the Circadian System.
Seasonal changes in light exposure have profound effects on behavioral and physiological functions in many species,

including effects on mood and cognitive function in humans. The mammalian brain's master circadian clock, the suprachiasmatic nucleus (SCN), transmits information about external light conditions to other brain regions, including some implicated in mood and cognition. Although the detailed mechanisms are not yet known, the SCN undergoes highly plastic changes at the cellular and network levels under different light conditions. We therefore propose that the SCN may be an essential mediator of the effects of seasonal changes of day length on mental health. In this review, we explore various forms of neuroplasticity that occur in the SCN and other brain regions to facilitate seasonal adaptation, particularly altered phase distribution of cellular circadian oscillators in the SCN and changes in hypothalamic neurotransmitter expression.

Rimonabant, a potent CB1 cannabinoid receptor antagonist, is a Gα protein inhibitor.
Rimonabant is a potent and selective cannabinoid CB1 receptor antagonist widely used in animal and clinical studies. Besides its antagonistic properties, numerous studies have shown that, at micromolar concentrations rimonabant behaves as an inverse agonist at CB1 receptors. The mechanism underpinning this activity is unclear. Here we show that micromolar concentrations of rimonabant inhibited Gα-type G proteins, resulting in a receptor-independent block of G protein signaling. Accordingly, rimonabant decreased basal and agonist stimulated [S]GTPγS binding to cortical membranes of CB1- and GABA-receptor KO mice and Chinese Hamster Ovary (CHO) cell membranes stably transfected with GABA or D2 dopamine receptors. The structural analog of rimonabant, AM251, decreased basal and baclofen-stimulated GTPγS binding to rat cortical and CHO cell membranes expressing GABA receptors. Rimonabant prevented G protein-mediated GABA and D2 dopamine receptor signaling to adenylyl cyclase in Human Embryonic Kidney 293 cells and to G protein-coupled inwardly rectifying K channels (GIRK) in midbrain dopamine neurons of CB1 KO mice. Rimonabant suppressed GIRK gating induced by GTPγS in CHO cells transfected with GIRK, consistent with a receptor-independent action. Bioluminescent resonance energy transfer (BRET) measurements in living CHO cells showed that, in presence or absence of co-expressed GABA receptors, rimonabant stabilized the heterotrimeric Gαi/o-protein complex and prevented conformational rearrangements induced by GABA receptor activation. Rimonabant failed to inhibit Gαs-mediated signaling, supporting its specificity for Gα-type G proteins. The inhibition of Gα protein provides a new site of rimonabant action that may help to understand its pharmacological and toxicological effects occurring at high concentrations.

In vitro and in vivo pharmacological characterization of SSD114, a novel GABAB positive allosteric modulator.
Positive allosteric modulators (PAMs) of the GABA receptor have emerged as a novel approach to the pharmacological manipulation of the GABA receptor, enhancing the effects of receptor agonists with few side effects. Here, we identified N-cyclohexyl-4-methoxy-6-(4-(trifluoromethyl)phenyl)pyrimidin-2-amine (SSD114) as a new compound with activity as a GABA PAM in in vitro and in vivo assays. SSD114 potentiated GABA-stimulated [S]GTPγS binding to native GABA receptors, whereas it had no effect when used alone. Its effect on GTPγS stimulation was suppressed when GABA-induced activation was blocked with CGP54626, a competitive antagonist of the GABA receptor. SSD114 failed to potentiate WIN55,212,2-, morphine- and quinpirole-induced [S]GTPγS binding to cortical and striatal membranes, respectively, indicating that it is a selective GABA PAM. Increasing SSD114 fixed concentrations induced a leftward shift of the GABA concentration-response curve, enhancing the potency of GABA rather than its efficacy. SSD114 concentration-response curves in the presence of fixed concentrations of GABA (1, 10, and 20μM) revealed a potentiating effect on GABA-stimulated binding of [S]GTPγS to rat cortical membranes, with EC values in the low micromolar range. Bioluminescence resonance energy transfer (BRET) experiments in Chinese Hamster Ovary (CHO)-cells expressing GABA receptors showed that SSD114 potentiates the GABA inhibition of adenylyl-cyclase mediated by GABA receptors. Our compound is also effective in vivo potentiating baclofen-induced sedation/hypnosis in mice, with no effect when tested alone. These findings indicate that SSD114, a molecule with a different chemical structure compared to known GABA PAMs, is a novel GABA PAM with potential usefulness in the GABA-receptor research field.

Native CB1 receptor affinity, intrinsic activity and accumbens shell dopamine stimulant properties of third generation SPICE/K2 cannabinoids: BB-22, 5F-PB-22, 5F-AKB-48 and STS-135.
In order to investigate the in vivo dopamine (DA) stimulant properties of selected 3rd generation Spice/K2 cannabinoids, BB-22, 5F-PB-22, 5F-AKB-48 and STS-135, their in vitro affinity and agonist potency at native rat and mice CB1 receptors was studied. The compounds bind with high affinity to CB1 receptors in rat cerebral cortex homogenates and stimulate CB1-induced [(35)S]GTPγS binding with high potency and efficacy. BB-22 and 5F-PB-22 showed the lowest Ki of binding to CB1 receptors (0.11 and 0.13 nM), i.e., 30 and 26 times lower respectively than that of JWH-018 (3.38 nM), and a potency (EC50,

2.9 and 3.7 nM, respectively) and efficacy (Emax, 217% and 203%, respectively) as CB1 agonists higher than JWH-018 (EC50, 20.2 nM; Emax, 163%). 5F-AKB-48 and STS-135 had higher Ki for CB1 binding, higher EC50 and lower Emax as CB1 agonists than BB-22 and 5F-PB-22 but still comparatively more favourable than JWH-018. The agonist properties of all the compounds were abolished or drastically reduced by the CB1 antagonist/inverse agonist AM251 (0.1 μM). No activation of G-protein was observed in CB1-KO mice. BB-22 (0.003-0.01 mg/kg i.v.) increased dialysate DA in the accumbens shell but not in the core or in the medial prefrontal cortex, with a bell shaped dose-response curve and an effect at 0.01 mg/kg and a biphasic time-course. Systemic AM251 (1.0 mg/kg i.p.) completely prevented the stimulant effect of BB-22 on dialysate DA in the NAc shell. All the other compounds increased dialysate DA in the NAc shell at doses consistent with their in vitro affinity for CB1 receptors (5F-PB-22, 0.01 mg/kg; 5F-AKB-48, 0.1 mg/kg; STS-135, 0.15 mg/kg i.v.). 3rd generation cannabinoids can be even more potent and super-high CB1 receptor agonists compared to JWH-018. Future research will try to establish if these properties can explain the high toxicity and lethality associated with these compounds.

Synthesis and pharmacological characterization of 2-(acylamino)thiophene derivatives as metabolically stable, orally effective, positive allosteric modulators of the GABAB receptor.
Two recently reported hit compounds, COR627 and COR628, underpinned the development of a series of 2-(acylamino)thiophene derivatives. Some of these compounds displayed significant activity in vitro as positive allosteric modulators of the GABAB receptor by potentiating GTPγS stimulation induced by GABA at 2.5 and 25 μM while failing to exhibit intrinsic agonist activity. Compounds were also found to be effective in vivo, potentiating baclofen-induced sedation/hypnosis in DBA mice when administered either intraperitoneally or intragastrically. Although displaying a lower potency in vitro than the reference compound GS39783, the new compounds 6, 10, and 11 exhibited a higher efficacy in vivo: combination of these compounds with a per se nonsedative dose of baclofen resulted in shorter onset and longer duration of the loss of righting reflex in mice. Test compounds showed cytotoxic effects at concentrations comparable to or higher than those of GS39783 or BHF177.

INFERRING LIGAND-RECEPTOR INTERACTIONS BETWEEN GABAERGIC AND GLUTAMATERGIC CELLS DURING SOMATOSENSORY CORTEX DEVELOPMENT

POSTER SESSION 06 - SECTION: E/I BALANCE AND PLASTICITY IN DEVELOPING CIRCUITS

Antoine De Chevigny[1], Rémi Mathieu[1], Ludovic Telley[2]
[1]INSERM, Inmed, Marseille, France, [2]University of Lausanne, Department Of Fundamental Neurosciences, Lausanne, Switzerland

The cerebral cortex contains two main neuronal types: excitatory glutamatergic neurons (GlutNs) & inhibitory GABAergic interneurons (INs) that each comprise different subtypes differentially distributing in six layers in a stereotyped fashion. GlutNs settle in the cortex before INs during cortex development, and several studies suggest that the preferred laminar allocation of IN subtypes to specific cortical layers is extrinsically regulated by GlutN subtypes. However, the cellular and molecular mechanisms by which different IN subtypes are allocated to specific cortical layers remain elusive. We hypothesize that a ligand/receptor (LR) molecular code orchestrates stereotypical laminar allocation and synaptic connectivity between INs and GlutNs. In order to identify this molecular code, we performed single-cell RNA sequencing from somatosensory cortex of mice at P0, P2, P5, P8, P16 and P30, which span the neonatal critical window of cortex invasion and synaptic connectivity by INs. By integrating to this collection published datasets corresponding to earlier and later time points using advanced bioinformatic methods, we could identify every main neuronal cell type and its transcriptomic evolution along 16 time points ranging from E11 to P56. To decrypt a putative cell-cell interaction molecular code by which IN subtypes would be recruited by and connect specific domains of GlutN subtypes during the neonatal critical window, we constructed a ligand-receptor atlas between these cell types. This bioinformatic ligand-receptor atlas unmasks shared and specific interactions that might instruct the stereotypic lamination and/or connectivity of neuronal subtypes.

Introduction: Appropriate excitatory/inhibitory balance is crucial for correct establishment of the neural circuit underlying normal brain development. Disruptions to this balance have been proposed in the aetiology of several neurodevelopmental disorders (NDDs), in which GABAergic signalling is impaired and neuronal morphology is changed. There are sex differences in incidence of NDDs and therefore it is possible that the neurobiological effect of altered GABA signalling is also sex-dependent. Here, we aimed to investigate whether pharmacological alteration of GABA signalling in early development results in sex-dependent changes in neuronal development and behaviour. Methods: Cortical neuronal cultures derived from postnatal day (P) 0 male and female mice were treated on Day-In-Vitro (DIV) 3 with $GABA_A$ receptor agonist muscimol at 0 and 5μM doses and assessed on DIV7. In vivo experiments involved performing intraperitoneal injections of 0.5mg/kg muscimol or saline in postnatal male and female mice P3, 4 and 5. Brains were collected for cortical structural analysis at P6 and 20. Behavioural studies were conducted at P60. Results: In the P0 cultures, treatment with 5μM of Muscimol reduced neural branching complexity of neurons cultured from male mice and reduced neurite length of females. In vivo experiments showed muscimol treatment increased cortical thickness and was statistically significant only within the male population. These changes were accompanied by behavioural sex-dependent impairments in adulthood. Conclusion: These data demonstrated that excitatory/inhibitory imbalance, impairs neural development by altering neuronal morpho-functional maturation in a sex-dependent manner, likely explaining the varied pathophysiology and neurodevelopmental diagnosis that result from the excitatory/inhibitory imbalance.

Cortical inhibitory GABAergic neurons are a highly heterogeneous cell population, whose specific connectivity patterns contribute to a division of labor within cortical circuits. Perisomatic inhibition is provided by parvalbumin (PV)- and cannabinoid receptor type 1 (CB1)-expressing basket cells (BCs). Despite the large body of evidence indicating the crucial role of PV cells in orchestrating cortical networks, the connectivity and function of CB1 BCs is still unknown. In order to identify the circuit properties of CB1 interneurons, we combined mouse genetics, *in vitro* whole-cell patch clamp recordings and *in vivo* two-photon calcium imaging in awake head-fixed mice during resting and running periods. We found that the intra- and infra-laminar connectivity pattern of CB1 BCs strongly differs between primary (V1) and medial secondary visual cortex (V2M). Tonic CB1 signaling suppresses GABA release from CB1 BCs onto layer 2/3 pyramidal neurons (PNs) in V2M, but not V1. In vivo, visual area-specific tonic CB1 signaling is responsible for a much higher but less coordinated spontaneous activity of PNs in V2M, as compared to V1. Numerical simulations confirmed that area-specific morpho-functional properties of CB1 interneurons are essential for the different cortical dynamics observed in V1 and V2M. We are currently investigating how CB1-mediated plasticity of inhibition affects locomotion-induced modulation of PN activity in the two areas. Our findings indicate that CB1 BCs operate a visual area-dependent dynamic inhibitory control of PNs that will likely play a major role in visual perception.

DORSAL RAPHE MODULATES THE ONGOING ACTIVITY, FUNCTIONAL CONNECTIVITY AND SENSORY RESPONSES OF ZEBRAFISH FOREBRAIN CIRCUITS

POSTER SESSION 06 - SECTION: MICROCIRCUITS AND NETWORK DYNAMICS

Our emotions have significant impact on the way we perceive the world surrounding us. In fact, making correct decisions by integrating the environmental stimuli with our internal state is crucial for survival. However, neural mechanisms underlying this integration are unknown. The dorsal raphe nucleus (DRN) is implicated in regulation of the internal state through its serotonergic projections. Here, we investigated the modulation of the ongoing forebrain activity, functional connectivity, sensory processing, and behavior by the serotonergic projections of the DRN. To do this, we chemogenetically ablated the serotonergic neurons in the DRN of the zebrafish, and compared the neural, and behavioral activity between the control animals and DRN-ablated animals. Using two-photon calcium imaging, we recorded the forebrain activity of 3 weeks-old juvenile zebrafish at cellular resolution, together with animal's locomotory behavior in virtual reality. We observed the DRN ablation led to prominent alterations in functional connectivity and sensory responses to aversive mechanical vibrations, across multiple forebrain regions associated with ancestral limbic circuitry. We also revealed that DRN ablation resulted in an increase in animals' behavioral response to novel environments and aversive mechanical vibrations. We are currently investigating how the activity of DRN relates to the activity of distinct forebrain circuitry. Taken together, our data point to broad regulation of forebrain circuits by DRN.

Ongoing habenular activity is driven by forebrain networks and modulated by olfactory stimuli.
Ongoing neural activity, which represents internal brain states, is constantly modulated by the sensory information that is generated by the environment. In this study, we show that the habenular circuits act as a major brain hub integrating the structured ongoing activity of the limbic forebrain circuitry and the olfactory information. We demonstrate that ancestral homologs of amygdala and hippocampus in zebrafish forebrain are the major drivers of ongoing habenular activity. We also reveal that odor stimuli can modulate the activity of specific habenular neurons that are driven by this forebrain circuitry. Our results highlight a major role for the olfactory system in regulating the ongoing activity of the habenula and the forebrain, thereby altering brain's internal states.

Functional properties of habenular neurons are determined by developmental stage and sequential neurogenesis.
The developing brain undergoes drastic alterations. Here, we investigated developmental changes in the habenula, a brain region that mediates behavioral flexibility during learning, social interactions, and aversive experiences. We showed that developing habenular circuits exhibit multiple alterations that lead to an increase in the structural and functional diversity of cell types, inputs, and functional modules. As the habenula develops, it sequentially transforms into a multisensory brain region that can process visual, olfactory, mechanosensory, and aversive stimuli. Moreover, we observed that the habenular neurons display spatiotemporally structured spontaneous activity that shows prominent alterations and refinement with age. These alterations in habenular activity are accompanied by sequential neurogenesis and the integration of distinct neural clusters across development. Last, we revealed that habenular neurons with distinct functional properties are born sequentially at distinct developmental time windows. Our results highlight a strong link between the functional properties of habenular neurons and their precise birthdate.

Quantifying indices of short- and long-range white matter connectivity at each cortical vertex.

Several neurodevelopmental diseases are characterized by impairments in cortical morphology along with altered white matter connectivity. However, the relationship between these two measures is not yet clear. In this study, we propose a novel methodology to compute and display metrics of white matter connectivity at each cortical point. After co-registering the extremities of the tractography streamlines with the cortical surface, we computed two measures of connectivity at each cortical vertex: the mean tracts' length, and the proportion of short- and long-range connections. The proposed measures were tested in a clinical sample of 62 patients with 22q11.2 deletion syndrome (22q11DS) and 57 typically developing individuals. Using these novel measures, we achieved a fine-grained visualization of the white matter connectivity patterns at each vertex of the cortical surface. We observed an intriguing pattern of both increased and decreased short- and long-range connectivity in 22q11DS, that provides novel information about the nature and topology of white matter alterations in the syndrome. We argue that the method presented in this study opens avenues for additional analyses of the relationship between cortical properties and patterns of underlying structural connectivity, which will help clarifying the intrinsic mechanisms that lead to altered brain structure in neurodevelopmental disorders.

Spontaneous Rapid Odor Source Localization Behavior Requires Interhemispheric Communication.
Navigation, finding food sources, and avoiding danger critically depend on the identification and spatial localization of airborne chemicals. When monitoring the olfactory environment, rodents spontaneously engage in active olfactory sampling behavior, also referred to as exploratory sniffing [1]. Exploratory sniffing is characterized by stereotypical high-frequency respiration, which is also reliably evoked by novel odorant stimuli [2, 3]. To study novelty-induced exploratory sniffing, we developed a novel, non-contact method for measuring respiration by infrared (IR) thermography in a behavioral paradigm in which novel and familiar stimuli are presented to head-restrained mice. We validated the method by simultaneously performing nasal pressure measurements, a commonly used invasive approach [2, 4], and confirmed highly reliable detection of inhalation onsets. We further discovered that mice actively orient their nostrils toward novel, previously unexperienced, smells. In line with the remarkable speed of olfactory processing reported previously [3, 5, 6], we find that mice initiate their response already within the first sniff after odor onset. Moreover, transecting the anterior commissure (AC) disrupted orienting, indicating that the orienting response requires interhemispheric transfer of information. This suggests that mice compare odorant information obtained from the two bilaterally symmetric nostrils to locate the source of the novel odorant. We further demonstrate that asymmetric activation of the anterior olfactory nucleus (AON) is both necessary and sufficient for eliciting orienting responses. These findings support the view that the AON plays an important role in the internostril difference comparison underlying rapid odor source localization.

Congenital heart disease is associated with reduced cortical and hippocampal volume in patients with 22q11.2 deletion syndrome.
There is increasing evidence that congenital heart disease (CHD) affects brain structure, but little is known about the long-term trajectory of brain maturation and its impact on the cognitive development of patients with CHD. We proposed to address this question in a longitudinally-followed cohort of individuals with 22q11.2 deletion syndrome (22q11DS), the most common microdeletion syndrome in humans.

Clinical and cognitive risk factors for psychotic symptoms in 22q11.2 deletion syndrome: a transversal and longitudinal approach.
22q11.2 deletion syndrome (22q11DS) is associated with increased risk for schizophrenia. Better identifying risk factors for the emergence of psychotic symptoms in this population is needed to improve clinical assessment and early interventions. Schizophrenia spectrum disorders, hallucinations and delusions were characterized in an original sample of 104 individuals with 22q11DS. Further analysis of positive and negative symptoms was performed in a subsample of 59 individuals. Finally, longitudinal data available in 56 patients were used to explore the developmental trajectories of psychotic symptoms as well as the associations between psychotic symptoms and cognitive functioning. Schizophrenia spectrum disorders and psychotic symptoms were frequent in adolescent and adults with 22q11DS. The severity of hallucinations and non-persecutory delusional ideas discriminated patients at ultra-high risk for conversion to psychosis. Whereas approximately one-third of patients experienced an emergence of psychotic symptoms during a 4-year interval, 20 % displayed transient symptoms. Individuals with psychotic symptoms were characterized by a lower cognitive functioning in the context of the 22q11DS. The present study adds important data on the characteristics and developmental trajectory of psychotic symptoms in this population. This information may ultimately help clinicians dealing with these patients to reduce the duration of untreated psychosis and improve outcome.

Sex differences in thickness, and folding developments throughout the cortex.
While significant differences in male and female brain structures have commonly been reported, only a few studies have focused on the sex differences in the way the cortex matures over time. Here, we investigated cortical thickness maturation between the age of 6 to 30 years, using 209 longitudinally-acquired brain MRI scans. Significant sex differences in the trajectories of cortical thickness change with age were evidenced using non-linear mixed effects models. Similar statistical analyses were computed to quantify the differences between cortical gyrification changes with age in males and females. During adolescence, we observed a statistically significant higher rate of cortical thinning in females compared to males in the right temporal regions, the left temporoparietal junction and the left orbitofrontal cortex. This finding is interpreted as a faster maturation of the social brain areas in females. Concomitantly, statistically significant sex differences in cortical folding changes with age were observed only in one cluster of the right prefrontal regions, suggesting that the mechanisms underlying cortical thickness and gyrification changes with age are quite distinct. Sexual dimorphism in the developmental course of the cortical maturation may be associated with the different age of onset and clinical presentation of many psychiatric disorders between males and females.

Limit-cycle-based control of the myogenic wingbeat rhythm in the fruit fly Drosophila.
In many animals, rhythmic motor activity is governed by neural limit cycle oscillations under the control of sensory feedback. In the fruit fly Drosophila melanogaster, the wingbeat rhythm is generated myogenically by stretch-activated muscles and hence independently from direct neural input. In this study, we explored if generation and cycle-by-cycle control of Drosophila's wingbeat are functionally separated, or if the steering muscles instead couple into the myogenic rhythm as a weak forcing of a limit cycle oscillator. We behaviourally tested tethered flying flies for characteristic properties of limit cycle oscillators. To this end, we mechanically stimulated the fly's 'gyroscopic' organs, the halteres, and determined the phase relationship between the wing motion and stimulus. The flies synchronized with the stimulus for specific ranges of stimulus amplitude and frequency, revealing the characteristic Arnol'd tongues of a forced limit cycle oscillator. Rapid periodic modulation of the wingbeat frequency prior to locking demonstrates the involvement of the fast steering muscles in the observed control of the wingbeat frequency. We propose that the mechanical forcing of a myogenic limit cycle oscillator permits flies to avoid the comparatively slow control based on a neural central pattern generator.

IR thermography-based monitoring of respiration phase without image segmentation.
Respiratory rate is an essential parameter in biomedical research and clinical applications. Most respiration measurement techniques in preclinical animal models require surgical implantation of sensors. Current clinical measurement modalities typically involve attachment of sensors to the patient, causing discomfort. We have previously developed a non-contact approach to measuring respiration phase in head-restrained rodents using infrared (IR) thermography. While the non-invasive nature of IR thermography offers many advantages, it also bears the complexity of extracting respiration signals from videos. Previously reported algorithms involve image segmentation to identify the nose in IR videos and extract breathing-relevant pixels which is particularly challenging if the videos have low contrast or suffer from suboptimal focusing.

Dopaminergic neurons of the substantia nigra pars compacta (SNc) and the ventral tegmental area (VTA) control orienting and approach toward important stimuli; this information is provided primarily by the superior colliculus (SC) which processes contralateral sensory data. Since interhemispheric imbalance of striatal dopamine release impacts the direction of animal's movement, we aimed to describe lateralization of neuronal pathway descending form SC to the dopaminergic system and its inhibitory input – the rostromedial tegmental nucleus (RMTg). The anatomy of the circuit was studied using anterograde, retrograde and transsynaptic tract tracing techniques. Multichannel electrophysiological recordings *in vivo* and *ex vivo*, combined with optogenetics were performed to study the circuit's physiology. We demonstrated that SC innervates predominantly ipsilateral SNc/VTA. Simultaneously, SC innervates contralateral RMTg; these recipient neurons send dense ipsilateral projection to SNc/VTA. Unilateral SC activation excited primarily contralateral RMTg neurons. SC stimulation *in vivo* was only slightly more prevalent in exciting ipsilateral dopaminergic neurons, however, activating SC-originating axon terminals *ex vivo* excited exclusively ipsilateral dopaminergic neurons. By manipulating SC-contralateral RMTg circuit we demonstrated SC's ability to inhibit contralateral dopaminergic neurons. Overall, SC may excite ipsilateral dopaminergic neurons directly while inhibiting contralateral ones indirectly via RMTg. This may cause an interhemispheric imbalance of striatal dopamine release, which in turn may affect animal's direction of movement and orientation. Since SC processes sensory information from the contralateral side of the body, the described brain circuit would promote orienting and approach in the direction of incoming sensory stimuli. Alpha-adrenergic receptor blockade in the VTA modulates fear memories and stress responses.
Activity of the ventral tegmental area (VTA) and its terminals has been implicated in the Pavlovian associative learning of both stressful and rewarding stimuli. However, the role of the VTA noradrenergic signaling in fear responses remains unclear. We aimed to examine how alpha-adrenergic receptor (α-AR) signaling in the VTA affects conditioned fear. The role of α-AR was assessed using the micro-infusions into the VTA of the selective antagonists (0.1-1μg/0.5μl prazosin and 1μg/0.5μl terazosin) in acquisition and expression of fear memory. In addition, we performed control experiments with α-AR blockade in the mammillary bodies (MB) - a brain region with α-AR expression adjacent to the VTA. Intra-VTA but not intra-MB α-AR blockade prevented formation and retrieval of fear memories. Importantly, local administration of α-AR antagonists did not influence footshock sensitivity, locomotion or anxiety-like behaviors. Similarly, α-AR blockade in the VTA had no effects on negative affect measured as number of 22kHz ultrasonic vocalizations during fear conditioning training. We propose that noradrenergic signaling in the VTA via α-AR regulates formation and retrieval of fear memories but not other behavioral responses to stressful environmental stimuli. It enhances the encoding of environmental stimuli by the VTA to form and retrieve conditioned fear memories and to predict future behavioral outcomes. Our results provide novel insight into the role of the VTA α-AR signaling in the regulation of stress responsiveness and fear memory.

Noradrenergic signaling in the VTA modulates cocaine craving.
Exposure to drug-associated cues evokes drug-seeking behavior and is regarded as a major cause of relapse. Conditional stimulus upregulates noradrenaline (NA) system activity, but the drug-seeking behavior depends particularly on phasic

dopamine signaling downstream from the ventral tegmental area (VTA). The VTA dopamine-ergic activity is regulated via the signaling of alpha -adrenergic and alpha -adrenergic receptors (α -ARs and α -ARs); thus, the impact of the conditional stimulus on drug-seeking behavior might involve NAergic signaling in the VTA. To date, the role of VTA ARs in regulating cocaine seeking was not studied. We found that cocaine seeking under extinction conditions in male Sprague-Dawley rats was attenuated by intra-VTA prazosin or terazosin-two selective α -AR antagonists. In contrast, cocaine seeking was facilitated by intra-VTA administration of the selective α -AR agonist phenylephrine as well as α -AR antagonist RX 821002, whereas the selective β-AR antagonist propranolol had no effects. In addition, blockade of α -AR in the VTA prevented α -AR antagonist-induced enhancement of cocaine seeking. Importantly, the potential non-specific effects of the VTA AR blockade on cocaine seeking could be excluded, because none of the AR antagonists influenced sucrose seeking under extinction conditions or locomotor activity in the open field test. These results demonstrate that NAergic signaling potently and selectively regulates cocaine seeking during early cocaine withdrawal via VTA α -AR and α -AR but not β-AR. Our findings provide new insight into the NAergic mechanisms that underlie cocaine craving.

Adrenergic Receptor Agonists' Modulation of Dopaminergic and Non-dopaminergic Neurons in the Ventral Tegmental Area.
The ventral tegmental area (VTA) neuronal population consists of dopaminergic (DAergic) and non-DAergic neurons (mainly GABAergic), the activity of which is intertwined with VTA behavioral functions. Both DAergic and GABAergic neurons in the VTA have been shown to express adrenergic receptors (ARs) and respond to AR stimulation. The aim of the present study was to demonstrate the effects of selective AR agonists on DAergic and non-DAergic neuronal activity in the central and lateral parts of the VTA using in vivo electrophysiological recording combined with microiontophoretic drug application in anaesthetized rats. Administration of phenylephrine, a selective α-AR agonist, while having an inhibitory effect on putative DAergic neurons (11% decrease in firing rate), induced a clear excitatory effect (59% increase in firing rate) on putative non-DAergic neurons. In contrast, application of clonidine, a selective α-AR agonist, or isoprenaline, a selective β-adrenergic receptor agonist, did not change the firing rate of either DAergic or non-DAergic neurons but influenced the firing pattern of non-DAergic cells only. Our results suggest that noradrenaline modulates activity of VTA neurons in vivo primarily via α, but also via β- and α-AR to a lesser extent. Furthermore, we show that α-AR activation has contrasting effects on putative DAergic and non-DAergic neurons. We hypothesize that the phenylephrine-induced inhibition of putative DAergic neurons results from activation of GABAergic terminals present at the site of drug application. Such a mechanism is further supported by the observed α-AR-induced excitation of putative GABAergic VTA neurons.

Effects of brief inhibition of the ventral tegmental area dopamine neurons on the cocaine seeking during abstinence.
Preclinical studies strongly suggest that cocaine seeking depends on the neuronal activity of the ventral tegmental area (VTA) and phasic dopaminergic (DA) signaling. Notably, VTA pharmacological inactivation or dopamine receptor blockade in the forebrain may induce behavioral inhibition in general and acute aversive states in particular, thus reducing cocaine seeking indirectly. Such artifacts hinder successful translation of these findings in clinical studies and practice. Here, we aimed to evaluate if dynamic VTA manipulations effectively reduce cocaine seeking. We used male tyrosine hydroxylase (TH) IRES-Cre rats along with optogenetic tools to inhibit directly and briefly VTA DA neurons during conditioned stimulus (CS)-induced cocaine seeking under extinction conditions. The behavioral effects of optogenetic inhibition were also assessed in the real-time dynamic place aversion, conditioned place aversion, and CS-induced food-seeking tests. We found that brief and nondysphoric/nonsedative pulses of VTA photo-inhibition (1 s every 9 s, ie, for 10% of time) attenuated CS-induced cocaine seeking under extinction conditions in rats expressing archaerhodopsin selectively on the TH neurons. Furthermore, direct inhibition of the VTA DA activity reduced CS-induced cocaine seeking 24 hours after photo-modulation. Importantly, such effect appears to be selective for cocaine seeking as similar inhibition of the VTA DA activity had no effect on CS-induced food seeking. Thus, briefly inhibiting VTA DA activity during CS-induced cocaine seeking drastically and selectively reduces seeking without behavioral artifacts such as sedation or dysphoria. Our results point to the therapeutic possibilities of coupling nonpharmacologic treatments with extinction training in reducing cocaine addiction.

Circadian actions of orexins on the retinorecipient lateral geniculate complex in rat.
Rhythmic processes in living organisms are controlled by biological clocks. The orexinergic system of the lateral hypothalamus carries circadian information to provide arousal for the brain during the active phase. Here, we show that orexins exert an excitatory action in three parts of the lateral geniculate nucleus (LGN), in particular upon directly retinorecipient neurons in the non-image forming visual structures. We provide evidence for the high nocturnal levels of

orexins with stable circadian expression of predominant orexin receptor 2 in the LGN. Our data additionally establish the convergence of orexinergic and pituitary adenylate cyclase (PAC)-activating peptide/PAC1 receptor systems (used by melanopsin-expressing retinal ganglion cells), which directly regulates responses to the retinal input. These results help us better understand circadian orexinergic control over the non-image forming subcortical visual system, forming the animal's preparedness for the behaviourally active night.

Superior Colliculus Controls the Activity of the Rostromedial Tegmental Nuclei in an Asymmetrical Manner.
Dopaminergic (DA) neurons of the midbrain are involved in controlling orienting and approach of animals toward relevant external stimuli. The firing of DA neurons is regulated by many brain structures; however, the sensory input is provided predominantly by the ipsilateral superior colliculus (SC). It is suggested that SC also innervates the contralateral rostromedial tegmental nucleus (RMTg)-the main inhibitory input to DA neurons. Therefore, this study aimed to describe the physiology and anatomy of the SC-RMTg pathway. To investigate the anatomic connections within the circuit of interest, anterograde, retrograde, and transsynaptic tract-tracing studies were performed on male Sprague Dawley rats. We have observed that RMTg is monosynaptically innervated predominantly by the lateral parts of the intermediate layer of the contralateral SC. To study the physiology of this neuronal pathway, we conducted electrophysiological experiments combined with optogenetics; the activity of RMTg neurons was recorded using silicon probes, while either contralateral or ipsilateral SC was optogenetically stimulated. Obtained results revealed that activation of the contralateral SC excites the majority of RMTg neurons, while stimulation of the ipsilateral SC evokes similar proportions of excitatory or inhibitory responses. Consequently, single-unit recordings showed that the activation of RMTg neurons innervated by the contralateral SC, or stimulation of contralateral SC-originating axon terminals within the RMTg, inhibits midbrain DA neurons. Together, the anatomy and physiology of the discovered brain circuit suggest its involvement in the orienting and motivation-driven locomotion of animals based on the direction of external sensory stimuli. Dopaminergic neurons are the target of predominantly ipsilateral, excitatory innervation originating from the superior colliculus. However, we demonstrate in our study that SC inhibits the activity of dopaminergic neurons on the contralateral side of the brain via the rostromedial tegmental nucleus. In this way, sensory information received by the animal from one hemifield could induce opposite effects on both sides of the dopaminergic system. It was shown that the side to which an animal directs its behavior is a manifestation of asymmetry in dopamine release between left and right striatum. Animals tend to move oppositely to the hemisphere with higher striatal dopamine concentration. This explains how the above-described circuit might guide the behavior of animals according to the direction of incoming sensory stimuli.

Daily changes in neuronal activities of the dorsal motor nucleus of the vagus under standard and high-fat diet.
Recently, we found that the dorsal vagal complex displays autonomous circadian timekeeping properties The dorsal motor nucleus of the vagus (DMV) is an executory part of this complex - a source of parasympathetic innervation of the gastrointestinal tract Here, we reveal daily changes in the neuronal activities of the rat DMV, including firing rate, intrinsic excitability and synaptic input - all of these peaking in the late day Additionally, we establish that short term high-fat diet disrupts these daily rhythms, boosting the variability in the firing rate, but blunting the DMV responsiveness to ingestive cues These results help us better understand daily control over parasympathetic outflow and provide evidence on its dependence on the high-fat diet ABSTRACT: The suprachiasmatic nuclei (SCN) of the hypothalamus function as the brain's primary circadian clock, but circadian clock genes are also rhythmically expressed in several extra-SCN brain sites where they can exert local temporal control over physiology and behaviour. Recently, we found that the hindbrain dorsal vagal complex possesses strong daily timekeeping capabilities, with the area postrema and nucleus of the solitary tract exhibiting the most robust clock properties. The possibility that the executory part of this complex - the dorsal motor nucleus of the vagus (DMV) - also exhibits daily changes has not been extensively studied. The DMV is the source of vagal efferent motoneurons that regulate gastric motility and emptying and consequently influence meal size and energy homeostasis. We used a combination of multi-channel electrophysiology and patch clamp recordings to gain insight into effects of time of day and diet on these DMV cells. We found that DMV neurons increase their spontaneous activity, excitability and responsiveness to metabolic neuromodulators at late day and this was paralleled with an enhanced synaptic input to these neurons. A high-fat diet typically damps circadian rhythms, but we found that consumption of a high-fat diet paradoxically amplified daily variation of DMV neuronal activity, while blunting the neurons responsiveness to metabolic neuromodulators. In summary, we show for the first time that DMV neural activity changes with time of day, with this temporal variation modulated by diet. These findings have clear implications for our understanding of the daily control of vagal efferents and parasympathetic outflow.

Rhythmic neuronal activities of the rat nucleus of the solitary tract are impaired by high-fat diet - implications for daily control of satiety.
Temporal partitioning of daily food intake is crucial for survival and involves the integration of internal circadian states and external influences such as the light-dark cycle and dietary composition. These intrinsic and extrinsic factors are interdependent with misalignment of circadian rhythms promoting body weight gain, while consumption of a calorie-dense diet elevates the risk of obesity and blunts circadian rhythms. Recently, we defined the circadian properties of the dorsal vagal complex of the brainstem, a structure implicated in the control of food intake and autonomic tone, but whether and how 24 h rhythms in this area are influenced by diet remains unresolved. Here we focused on a key structure of this complex, the nucleus of the solitary tract (NTS). We used a combination of immunohistochemical and electrophysiological approaches together with daily monitoring of body weight and food intake to interrogate how the neuronal rhythms of the NTS are affected by a high-fat diet. We report that short-term consumption of a high-fat diet increases food intake during the day and blunts NTS daily rhythms in neuronal discharge. Additionally, we found that a high-fat diet dampens NTS responsiveness to metabolic neuropeptides, and decreases orexin immunoreactive fibres in this structure. These alterations occur without prominent body weight gain, suggesting that a high-fat diet acts initially to reduce activity in the NTS to disinhibit mechanisms that suppress daytime feeding. KEY POINTS: The dorsal vagal complex of the rodent hindbrain possesses intrinsic circadian timekeeping mechanisms In particular, the nucleus of the solitary tract (NTS) is a robust circadian oscillator, independent of the master suprachiasmatic clock Here, we reveal that rat NTS neurons display timed daily rhythms in their neuronal activity and responsiveness to ingestive cues These daily rhythms are blunted or eliminated by a short-term high-fat diet, together with increased consumption of calories during the behaviourally quiescent day Our results help us better understand the circadian control of satiety by the brainstem and its malfunctioning under a high-fat diet.

Daily coordination of orexinergic gating in the rat superior colliculus-Implications for intrinsic clock activities in the visual system.
The orexinergic system delivers excitation for multiple brain centers to facilitate behavioral arousal, with its malfunction resulting in narcolepsy, somnolence, and notably, visual hallucinations. Since the circadian clock underlies the daily arousal, a timed coordination is expected between the orexin system and its target subcortical visual system, including the superior colliculus (SC). Here, we use a combination of electrophysiological, immunohistochemical, and molecular approaches across 24 h, together with the neuronal tract-tracing methods to investigate the daily coordination between the orexin system and the rodent SC. Higher orexinergic input was found to occur nocturnally in the superficial layers of the SC, in time for nocturnal silencing of spontaneous firing in this visual brain area. We identify autonomous daily and circadian expression of clock genes in the SC, which may underlie these day-night changes. Additionally, we establish the lateral hypothalamic origin of the orexin innervation to the SC and that the SC neurons robustly respond to orexin A via OX receptor in both excitatory and GABA receptor-dependent inhibitory manners. Together, our evidence elucidates the combination of intrinsic and extrinsic clock mechanisms that shape the daily function of the visual layers of the SC.

Bidirectional Communication between the Pontine Nucleus Incertus and the Medial Septum Is Carried Out by Electrophysiologically-Distinct Neuronal Populations.
Theta oscillations are key brain rhythm involved in memory formation, sensorimotor integration, and control of locomotion and behavioral states. Generation and spatiotemporal synchronization of theta oscillations rely on interactions between brain nuclei forming a large neural network, which includes pontine nucleus incertus (NI). Here we identified distinct populations of NI neurons, based on the relationship of their firing to hippocampal waves, with a special focus on theta oscillations, and the direction and type of interaction with the medial septum (MS) in male, urethane-anesthetized rats. By recording NI neuronal firing and hippocampal LFP, we described NI neurons that fire action potentials in a theta phase-independent or theta phase-locked and delta wave-independent or delta wave-locked manner. Among hippocampal activity-independent NI neurons, irregular, slow-firing, and regular, fast-firing cells were observed, while hippocampal oscillation-/wave-locked NI neurons were of a bursting or nonbursting type. By projection-specific optotagging, we revealed that only fast-firing theta phase-independent NI neurons innervate the MS, rarely receiving feedback information. In contrast, the majority of theta-bursting NI neurons were inhibited by MS stimulation, and this effect was mediated by direct GABAergic input. Described NI neuronal populations differ in reciprocal connections with the septohippocampal system, plausibly forming separate neuronal loops.

Our results suggest that theta phase-independent NI neurons participate in theta rhythm generation through direct innervation of the MS, while theta-bursting NI neurons further transmit the rhythmic signal received from the MS to stabilize and/or strengthen rhythmic activity in other structures. The generation and spatiotemporal synchronization of theta oscillations rely on interactions between nuclei forming a large neural network, part of which is the pontine nucleus incertus (NI). Here we describe that within NI there are populations of neurons that can be distinguished based on the relationship of their firing to hippocampal theta oscillations and delta waves. We show that these neuronal populations largely do not have reciprocal connections with the septohippocampal system, but form separate neuronal loops. Our results suggest that medial septum (MS)-projecting, fast-firing, theta phase-independent NI neurons may participate in theta rhythm generation through direct innervation of the MS, while theta-bursting NI neurons may further transmit the rhythmic signal received from the MS to other structures.

WILL WORK FOR EFFECT: HOW RESPONSE-CONTINGENT PERCEPTUAL EFFECTS REINFORCE BEHAVIOR

POSTER SESSION 06 - SECTION: MICROCIRCUITS AND NETWORK DYNAMICS

Rivka Aviv, Baruch Eitam, Oded Klavir
University of Haifa, Psychology, Haifa, Israel

Successfully manipulating one's environment has previously been argued to be inherently rewarding, assumingly affecting performance by influencing patterns of response selection. Studies in humans have shown that information about the effectiveness of a response, even when it merely indicates that the response led to a perceptual change (e.g., a brief 'flash'), reinforces the response that is credited with this, value-neutral, effect (i.e., effectiveness-feedback). On the one hand, the motivating effect of being effective could be a higher order phenomena relying on a higher cognitive mechanisms, yet on the other, this could be a basic mechanism perfecting and shaping even the simplest responses. In order to test this question, in this study, we tested the effectiveness-feedback in mice using a newly designed behavioral task. Based on previous work in humans, which established that only immediate response-effects were reinforcing we predicted that effectiveness-feedback, in the form of light appearing immediately after a lever press, will reinforce the mice's behavior to press the relevant lever more than a delayed appearance of light (delayed effectiveness-feedback). The behavioral experiment provides substantial support that this is indeed the case, implying that the (motivating) effects on behavior are driven by environmental information about one's own effectiveness. The presence of such an effect in mice indicates for the first time, that as in humans, other animals are also intrinsically motivated by an effectiveness-feedback with striking resemblance to the parameters that determine 'effects' in humans. This suggests that effectiveness is a basic mechanism in shaping behavior.

INPUT AND OUTPUT CONNECTIVITY MAPPING REVEALS INTEGRATING PROPERTIES OF CORTICOCLAUSTRAL AND INTRACLAUSTRAL CIRCUITS

POSTER SESSION 06 - SECTION: MICROCIRCUITS AND NETWORK DYNAMICS

Andrew Shelton, David Oliver, Simon Butt, Adam Packer
University of Oxford, Department Of Physiology, Anatomy, And Genetics, Oxford, United Kingdom

The claustrum is highly interconnected with many structures in the brain, but our knowledge of the organizing principles governing its vast connectivity remains incomplete. The present study investigates the architecture of circuits between the claustrum and neocortex and within the claustrum itself. Immunohistochemistry, retrograde tracing, *in vitro* whole-cell patch-clamp electrophysiology, dual-color optogenetic circuit mapping, and *in vivo* calcium imaging of neural activity were used to assess whether claustrum neurons combine inputs from multiple cortical areas and what impact claustrum neurons have on the cortex. We determined that individual claustrum neurons frequently integrate inputs from more than one cortical site, most commonly between regions of the frontal cortex. Additionally, we found that neurons in the claustrum receive inputs from an array of sensory and associative cortical areas, albeit to a lesser extent. Retrograde labeling further indicated that input integration from frontal cortical regions depends on the output target of claustrum neurons. Optogenetic mapping revealed that intraclaustral connectivity was far more frequent than previously reported in coronal slices, particularly among neurons that did not share the same output target. Finally, individual claustrum axons recorded *in vivo* displayed clear responses to multiple sensory modalities. Our findings shed light on the organizing principles of claustrum connectivity, demonstrating a clear relationship between cortical projections, local claustral connectivity, and claustral outputs.

POSITIVE AND SHARP BIPHASIC EXTRACELLULAR WAVEFORMS CORRESPOND TO DENDRITIC AND AXONAL SPIKES

POSTER SESSION 06 - SECTION: MICROCIRCUITS AND NETWORK DYNAMICS

Shirly Someck[1,2], Amir Levi[1,2], Lidor Spivak[1,2], Roni Gattegno[1,2], Eran Stark[1,2]
[1]Tel Aviv University, Physiology And Pharmacology, Tel Aviv, Israel, [2]Tel Aviv University, Sagol School Of Neuroscience, tel aviv, Israel

In extracellular models, spike waveforms differ between neuronal compartments: negative peaks near the soma, and positive or biphasic waveforms next to other compartments. Experimental reports suggest that both positive and biphasic waveforms correspond to axonal potentials. However, the prior work employed relatively small datasets or anesthetized preparations, and did not monitor simultaneously multiple waveforms of the same unit. Here, we analyzed 10,199 units recorded by high-density silicon probes from neocortex and hippocampus of 17 freely-moving mice. We divided units into three categories based on the waveform recorded at the highest amplitude channel: negative units ("Nunits"), sharp biphasic units, and positive units ("Punits"). We found 869 biphasic units, 648 Punits, and 889 "multipolar" Nunits with simultaneously-monitored biphasic or positive spikes. Punits exhibited firing rates and refractory periods similar to Nunits, but sharper waveforms which were compactly distributed in space. In multipolar units, positive spikes preceded negative spikes by under 0.1 ms, with jitter under 0.2 ms. This suggest that positive spikes represent the extracellular signature of dendritic return currents resulting from spikes generated at the axon initial segment. In CA1 recordings, the fraction of biphasic units was highest in stratum radiatum. In some cases, spikes of physiologically-verified inhibitory cells were followed by spiking of biphasic units with sub-millisecond delay and jitter. These observations suggest that biphasic spikes correspond to axonal potentials. Together, the results suggest that positive and sharp biphasic extracellular spikes represent dendritic and axonal potentials, respectively.

Outan: An On-Head System for Driving µLED Arrays Implanted in Freely Moving Mice.
In the intact brain, neural activity can be recorded using sensing electrodes and manipulated using light stimulation. Silicon probes with integrated electrodes and µLEDs enable the detection and control of neural activity using a single implanted device. Miniaturized solutions for recordings from small freely moving animals are commercially available, but stimulation is driven by large, stationary current sources. We designed and fabricated a current source chip and integrated it into a headstage PCB that weighs 1.37 g. The proposed system provides 10-bit resolution current control for 32 channels, driving µLEDs with up to 4.6 V and sourcing up to 0.9 mA at a refresh rate of 5 kHz per channel. When calibrated against a µLED probe, the system allows linear control of light output power, up to 10 µW per µLED. To demonstrate the capabilities of the system, synthetic sequences of neural spiking activity were produced by driving multiple µLEDs implanted in the hippocampal CA1 area of a freely moving mouse. The high spatial, temporal, and amplitude resolution of the system provides a rich variety of stimulation patterns. Combined with commercially available sampling headstages, the system provides an easy to use back-end, fully utilizing the bi-directional potential of integrated opto-electronic arrays.

THE NEURAL CIRCUIT OF ENHANCED POST-TRAUMATIC THREAT DETECTION

POSTER SESSION 06 - SECTION: MICROCIRCUITS AND NETWORK DYNAMICS

Ami Ritter, Oded Klavir
University of Haifa, School Of Psychological Sciences, Haifa, Israel

Anxiety disorders, and PTSD particularly are associated with heightened levels of arousal. This study aimed to investigate neural networks, which regulate threat detection, and long term changes after traumatic experiences. We were interested in neural activity in the cortico-basal ganglia related circuits which may facilitate threat detection by inhibiting the nigro-tectal pathway including the substantia-nigra(SC) and its connection to the superior colliculus(SC). The striatum, the main input region of the basal-ganglia receives projections from the medial-prefrontal-cortex(mPFC), potentially allowing the introduction of affective information into the basal-ganglia to modulate threat detection and behavioral responses thereto. We combined in-vivo electrophysiology and optogenetics, while behaviorally assessing threat detection mice, post an inescapable foot-shock. A new paradigm was developed, involving a randomly moving robotic bug(robo-beetle), creating incidental interactions with the mouse in the arena. We found significant differences in fear related behaviors, such as altered timing and distance of avoidance and escaping onset, higher fleeing velocities following anticipated contacts with the robo-beetle and overall, more instances of fear related actions following shock. A direct mPFC–SC pathway, as well as a yet to be described connection, branching out of the mPFC onto both, the DMS and SC was found. Most recorded SC neurons precede fleeing onsets by few milliseconds and correlate with the anxiety induced shifts in flight initiation timing, as well as defensive distance. Results suggest a direct contribution of SC units in flight behavior, as well as plastic changes in the top down connectivity from the mPFC onto the SC, involved in enhanced threat detection.

Methylphenidate and environmental enrichment ameliorate the deleterious effects of prenatal stress on attention functioning. Either pre- or post-natal environmental factors seem to play a key role in brain and behavioral development and to exert long-term effects. Increasing evidence suggests that exposure to prenatal stress (PS) leads to motor and learning deficits and elevated anxiety, while enriched environment (EE) shows protective effects. The dopaminergic system is also sensitive to environmental life circumstances and affects attention functioning, which serves as the preliminary gate to cognitive processes. However, the effects of methylphenidate (MPH) on the dopaminergic system and attentional functioning, in the context of these life experiences, remain unclear. Therefore, we aimed to examine the effects of EE or PS on distinct types of attention, along with possible effects of MPH exposure. We found that PS impaired selective attention as well as partial sustained attention, while EE had beneficial effects. Both EE and MPH ameliorated the deleterious effects of PS on attention functioning. Considering the possible psychostimulant effect of MPH, we examined both anxiety-like behavior as well as motor learning. We found that PS had a clear anxiogenic effect, whereas EE had an anxiolytic effect. Nevertheless, the treatment with both MPH and/or EE recovered the deleterious effects of PS. In the motor-learning task, the PS group showed superior performance while MPH led to impaired motor learning. Performance decrements were prevented in both the PS + MPH and EE + MPH groups. This study provides evidence that peripubertal exposure to EE (by providing enhanced sensory, motor, and social opportunities) or MPH treatments might be an optional therapeutic intervention in preventing the PS long-term adverse consequences.

UNDERSTANDING THE INTERPLAY BETWEEN FEAR ANXIETY AND THE STEREOTYPIC BEHAVIOR OF GROOMING IN DAT-CRE MICE

POSTER SESSION 06 - SECTION: MICROCIRCUITS AND NETWORK DYNAMICS

Lior Givon, Oded Klavir
University of Haifa, School Of Psychological Sciences, Haifa, Israel

Repetitive behavior is an integral part of several neurological/mental disorders. In disorders such as Obsessive Compulsive Disorder (OCD) or syndromes like Tourette, patients are unable to cease some repetitive activities, despite a great inconvenience, impaired functioning, injuries and social problems. Excessive repetitive behavior has been explained as both impairment in reward processing and an imbalance between Stimuli-Response (S-R) and Action-Outcome (A-O) systems. Striatal activity, and in particular Dopamine (DA) projections to the Dorsal Striatum (DS) and ventral (VS) striatum has been tied with reward processing and S-R/A-O behaviors. In addition, evidence show that DA projections to the striatum are involved in psychopathology such as OCD and Tourette. Anxiety is known to exacerbate compulsive behaviors. It has been suggested that fear modulate S-R/A-O behaviors by affecting striatal activity. In the current study we are focused on the role of striatal Afferent DA projections in the interaction between anxiety and grooming behavior – induced and spontaneous. We bilaterally injected 80 DAT-Cre mice with retrograde AAV containing hM4D to either the DS or the VS. All animals went through a behavioral paradigm involving fear conditioning, which allowed us to test the augmentation effects of fear and anxiety on grooming behavior and the role played in this interaction by DA neurons belonging to distinct pathways. We tested different aspects of grooming behavior (duration, timing, bout lengths) and found different effects for both DA pathways in different types of grooming and the interaction between with the effects of anxiety.

CONTROL OF NEOCORTICAL TOP-DOWN INFORMATION BY NDNF INTERNEURONS IN LAYER 1

POSTER SESSION 06 - SECTION: MICROCIRCUITS AND NETWORK DYNAMICS

Jan Hartung[1], Anna Schroeder[2], Rodrigo Alejandro Pérez Vázquez[1], Johannes Letzkus[1]
[1]University of Freiburg, Institute For Physiology, Dept. I, Freiburg, Germany, [2]Max Planck Institute for Brain Research, Synaptic Plasticity, Frankfurt am Main, Germany

Mounting evidence identifies neocortical layer 1 (L1) as a central hub for processing of internally-generated top-down information encoding previous experiences and current aims. These signals are thought to be controlled and shaped by L1 interneurons, the only resident neurons in this lamina. Here we leverage our recent identification of the first selective marker for a subset of L1 interneurons (neuron derived neurotrophic factor, NDNF) to dissect the connectivity, potential subtypes and circuit function of these neurons. *In vitro* slice recordings in combination with optogenetics indicate that, in addition to their established output to pyramidal neuron dendrites, NDNF interneurons also supply inhibition to interneurons in deeper layers expressing the markers parvalbumin (PV) and vasoactive intestinal peptide (VIP). Large-scale *in vivo* recordings together with optogenetics reveal how this widespread connectivity combines to shape the circuit function of NDNF cells. Since recent research implies the existence of NDNF interneuron subpopulations distinguished by the expression of neuropeptide Y (NDNF/NPY cells), we furthermore validate and employ intersectional viral targeting. Our data indicate that both NDNF and NDNF/NPY interneurons comprise a large proportion of late-spiking cells, and provide inhibitory inputs to L2/3 pyramidal neurons. Intriguingly, NDNF and NDNF/NPY interneurons engage in persistent, autonomous firing after repeated stimulation, a feature we observe only rarely in PV cells and not in non-fast spiking interneurons and pyramidal cells. In conclusion, NDNF and likely NDNF/NPY interneurons control large parts of the circuit, enabling top-down input to these cells to function as a master regulator in neocortex.

OPTOGENETIC DECONSTRUCTION OF CORTICAL OLFACTORY CODES

POSTER SESSION 06 - SECTION: MICROCIRCUITS AND NETWORK DYNAMICS

Robin Blazing
Duke University, Neurobiology, Durham, United States of America

Many neural circuits exhibit reproducible sequences of activity that correlate with perception, action, or distinct internal states. Neural sequences lasting on the order of tens to hundreds of milliseconds are proposed to mediate essential cognitive processes including navigation, memory encoding and retrieval, and sensory discrimination. However, the extent to which the temporal structure of these sequences impacts the activity of downstream reader circuits remains relatively unexplored. In the rodent olfactory system, odors activate stereotyped spatiotemporal sequences of olfactory bulb glomeruli that project to downstream piriform cortex (PCx). Using targeted patterned optogenetic stimulation of glomeruli in mice while recording from large populations of PCx neurons, we have revealed that neural activity in PCx is highly sensitive to the specific timing of sequences of glomerular inputs with millisecond resolution. We hypothesize that the temporal specificity of these responses is implemented by the interplay of intra-cortical excitation and inhibition which, together, form a delay-line architecture that governs the temporal selectivity of PCx neurons. We are currently testing this hypothesis by stimulating sequences of glomeruli while optogenetically suppressing either PCx inhibitory interneurons or subsets of excitatory PCx cells. These findings will provide novel insights into the computational principles and mechanisms that underlie the encoding and decoding of precise neural sequences in cortical circuits.

Odor coding in piriform cortex: mechanistic insights into distributed coding.
Olfaction facilitates a large variety of animal behaviors such as feeding, mating, and communication. Recent work has begun to reveal the logic of odor transformations that occur throughout the olfactory system to form the odor percept. In this review, we describe the coding principles and mechanisms by which the piriform cortex and other olfactory areas encode three key odor features: odor identity, intensity, and valence. We argue that the piriform cortex produces a multiplexed odor code that allows non-interfering representations of distinct features of the odor stimulus to facilitate odor recognition and learning, which ultimately drives behavior.

NEURONAL AND HEMODYNAMIC RESTING STATE ACTIVITY DURING ACUTE HYPOXIA USING CALCIUM AND INTRINSIC OPTICAL IMAGING IN MICE

POSTER SESSION 06 - SECTION: MICROCIRCUITS AND NETWORK DYNAMICS

Marleen Bakker[1], Ismaël Djerourou[2], Samuel Belanger[3], Frédéric Lesage[1], Matthieu Vanni[2]
[1]Polytechnique, Biomedical Engineering, Montréal, Canada, [2]Université de Montréal, Optometry, Montréal, Canada, [3]Labeo Technologies inc., Research & Development, Montréal, Canada

The brain uses the most oxygen of all organs in the human body. A hindered oxygen supply to the brain can cause a lower cognition. How this decrease in cognition happens during hypoxic episodes is still obscure, but might be related with altered functional connectivity of the brain. Even in the absence of stimuli, the brain has a certain activation pattern known as the resting state network (RSN). These can be observed both through neuronal and hemodynamic activity using calcium and intrinsic optical imaging respectively. In this study, we aimed to use these tools to better understand how the RSN are modified under different levels of hypoxia in awake mice. To do so, we exposed 8 mice to different levels of oxygen (12%, 10% and 8%) in an enclosure with controlled environment. At the same time, we monitored changes in calcium activity (using GCaMP6), HbO and HbR on the surface of the cortex with a multiwavelength intrinsic optical imaging. We compared these findings with spontaneous activity during normoxia. We found decreases in the hemodynamic network activity, that were consistent over mice. The changes became more apparent with lower levels of oxygen. This suggests that oxygen levels alter RSN dynamics, which could be linked to decreased cognition. By investigating the functional connectivity changes during lowered levels of atmospheric oxygen, we shed light on the mechanisms in play during global hypoxia. This opens the door to further works into the study of neurovascular coupling and the neural substrate of consciousness.

RETROSPLENIAL CORTEX ACTIVITY: A HUB IN A PARADOXICAL SLEEP NETWORK?

POSTER SESSION 06 - SECTION: MICROCIRCUITS AND NETWORK DYNAMICS

Micaela Borsa, Mattia Aime, Niccolo Calcini, Antoine Adamantidis
University of Bern, Department Of Neurology, Bern, Switzerland

Rapid eye movement (REM, also called paradoxical) sleep correlates with enhanced cellular activity of region-specific thalamo-cortical circuit and subcortical structures including the hippocampus, midbrain or hypothalamus. This REM sleep specific neuronal activity is hypothesized to promote structural plasticity and provide a window for the consolidation of contextual and emotional memories previously acquired during wakefulness, yet the underlying mechanism remains unclear. Amongst the cortical structures, the activity of neurons located in the retrosplenial cortex (RSC) is increased during REM sleep. Yet, cortical single cell-to-whole brain circuit connections and its role in REM sleep function remains unknown. Here we characterized the activity of RSC microcircuit across the sleep-wake cycle using simultaneous 2-photon calcium imaging and electrophysiological recordings in spontaneously head-restrained sleeping mice. We observed a REM sleep-specific reduction of pyramidal cell somatic activity concomitant to the activation of the interneurons expressing either parvalbumin, somatostatin or vasoactive intestinal peptide. Collectively, these observations suggested a region-specific regulation of excitatory/inhibitory balance in RSC during REM sleep that may contribute to information integration, memory consolidation and ultimately behavioural optimization.

Sharp wave-ripple (SPW-R) complexes are observed in the mammalian hippocampus on EEG during slow-wave sleep and immobility. These synchronous population discharges are considered to play an essential role in memory consolidation and the replay of wakefulness-acquired memory. An in vitro SPW-R model was investigated on rat hippocampal slices using a 24-channel linear electrode. Instead of assuming a classical trisynaptic circle of information flow from the DG to the CA3 (Type I), our studies showed that SPW-Rs could also be propagated in the opposite direction (Type II), or generated simultaneously in both areas (Type III). Based on these results, it can be stated that bidirectional information flow occurs between the DG and the CA3 region of the rat hippocampus. At the initiation site of the SPW-R complexes, more cells were activated than at other regions. Pyramidal cells of the CA3 fired more and showed denser connectivity than granule cells of the DG. A metabotropic glutamate receptor agonist, DCG-IV was used to investigate the role of the mossy fibres in the generation of SPW-Rs. In DCG-IV bath, the recurrence frequency of Type I SPW-Rs increased, while that of Type II SPW-Rs showed a slight drop. The propagation of SPW-Rs decelerated, while the LFPg deflections and the superimposed multiunit activities were reduced. The role of reverse information flow might be to intensify the information packages transmitted by the SPW-R complexes by adding another network to the trisynaptic circle for more efficient memory consolidation.

Perisomatic Inhibition and Its Relation to Epilepsy and to Synchrony Generation in the Human Neocortex.
Inhibitory neurons innervating the perisomatic region of cortical excitatory principal cells are known to control the emergence of several physiological and pathological synchronous events, including epileptic interictal spikes. In humans, little is known about their role in synchrony generation, although their changes in epilepsy have been thoroughly investigated. This paper demonstraits how parvalbumin (PV)- and type 1 cannabinoid receptor (CB1R)-positive perisomatic interneurons innervate pyramidal cell bodies, and their role in synchronous population events spontaneously emerging in the human epileptic and non-epileptic neocortex, in vitro. Quantitative electron microscopy showed that the overall, PV+ and CB1R+ somatic inhibitory inputs remained unchanged in focal cortical epilepsy. On the contrary, the size of PV-stained synapses increased, and their number decreased in epileptic samples, in synchrony generating regions. Pharmacology demonstrated-in conjunction with the electron microscopy-that although both perisomatic cell types participate, PV+ cells have stronger influence on the generation of population activity in epileptic samples. The somatic inhibitory input of neocortical pyramidal cells remained almost intact in epilepsy, but the larger and consequently more efficient somatic synapses might account for a higher synchrony in this neuron population. This, together with epileptic hyperexcitability, might make a cortical region predisposed to generate or participate in hypersynchronous events.

The neural tissue around SU-8 implants: A quantitative in vivo biocompatibility study.
The use of SU-8 material in the production of neural sensors has grown recently. Despite its widespread application, a detailed systematic quantitative analysis concerning its biocompatibility in the central nervous system is lacking. In this immunohistochemical study, we quantified the neuronal preservation and the severity of astrogliosis around SU-8 devices implanted in the neocortex of rats, after a 2 months survival. We found that the density of neurons significantly decreased up

to a distance of 20 µm from the implant, with an averaged density decrease to 24 ± 28% of the control. At 20 to 40 µm distance from the implant, the majority of the neurons was preserved (74 ± 39% of the control) and starting from 40 µm distance from the implant, the neuron density was control-like. The density of synaptic contacts - examined at the electron microscopic level - decreased in the close vicinity of the implant, but it recovered to the control level as close as 24 µm from the implant track. The intensity of the astroglial staining significantly increased compared to the control region, up to 560 µm and 480 µm distance from the track in the superficial and deep layers of the neocortex, respectively. Electron microscopic examination revealed that the thickness of the glial scar was around 5-10 µm thin, and the ratio of glial processes in the neuropil was not more than 16% up to a distance of 12 µm from the implant. Our data suggest that neuronal survival is affected only in a very small area around the implant. The glial scar surrounding the implant is thin, and the presence of glial elements is low in the neuropil, although the signs of astrogliosis could be observed up to about 500 µm from the track. Subsequently, the biocompatibility of the SU-8 material is high. Due to its low cost fabrication and more flexible nature, SU-8 based devices may offer a promising approach to experimental and clinical applications in the future.

Presence of synchrony-generating hubs in the human epileptic neocortex.
•Initiation of pathological synchronous events such as epileptic spikes and seizures is linked to the hyperexcitability of the neuronal network in both humans and animals. •In the present study, we show that epileptiform interictal-like spikes and seizures emerged in human neocortical slices by blocking GABA receptors, following the disappearance of the spontaneously occurring synchronous population activity. •Large variability of temporally and spatially simple and complex spikes was generated by tissue from epileptic patients, whereas only simple events appeared in samples from non-epileptic patients. •Physiological population activity was associated with a moderate level of principal cell and interneuron firing, with a slight dominance of excitatory neuronal activity, whereas epileptiform events were mainly initiated by the synchronous and intense discharge of inhibitory cells. •These results help us to understand the role of excitatory and inhibitory neurons in synchrony-generating mechanisms, in both epileptic and non-epileptic conditions.

Hyperexcitability of the network contributes to synchronization processes in the human epileptic neocortex.
Hyperexcitability and hypersynchrony of neuronal networks are thought to be linked to the generation of epileptic activity in both humans and animal models. Here we show that human epileptic postoperative neocortical tissue is able to generate two different types of synchronies in vitro. Epileptiform bursts occurred only in slices derived from epileptic patients and were hypersynchronous events characterized by high levels of excitability. Spontaneous population activity emerged in both epileptic and non-epileptic tissue, with a significantly lower degree of excitability and synchrony, and could not be linked to epilepsy. These results help us to understand better the role of excitatory and inhibitory neuronal circuits in the generation of population events, and to define the subtle border between physiological and pathological synchronies.

The hippocampal CA3 region can generate two distinct types of sharp wave-ripple complexes, in vitro.
Hippocampal sharp wave-ripples (SPW-Rs) occur during slow wave sleep and behavioral immobility and are thought to play an important role in memory formation. We investigated the cellular and network properties of SPW-Rs with simultaneous laminar multielectrode and intracellular recordings in a rat hippocampal slice model, using physiological bathing medium. Spontaneous SPW-Rs were generated in the dentate gyrus (DG), CA3, and CA1 regions. These events were characterized by a local field potential gradient (LFPg) transient, increased fast oscillatory activity and increased multiple unit activity (MUA). Two types of SPW-Rs were distinguished in the CA3 region based on their different LFPg and current source density (CSD) pattern. Type 1 (T1) displayed negative LFPg transient in the pyramidal cell layer, and the associated CSD sink was confined to the proximal dendrites. Type 2 (T2) SPW-Rs were characterized by positive LFPg transient in the cell layer, and showed CSD sinks involving both the apical and basal dendrites. In both types, consistent with the somatic CSD source, only a small subset of CA3 pyramidal cells fired, most pyramidal cells were hyperpolarized, while most interneurons increased firing rate before the LFPg peak. Different neuronal populations, with different proportions of pyramidal cells and distinct subsets of interneurons were activated during T1 and T2 SPW-Rs. Activation of specific inhibitory cell subsets-with the possible leading role of perisomatic interneurons-seems to be crucial to synchronize distinct ensembles of CA3 pyramidal cells finally resulting in the expression of different SPW-R activities. This suggests that the hippocampus can generate dynamic changes in its activity stemming from the same excitatory and inhibitory circuits, and so, might provide the cellular and network basis for an input-specific and activity-dependent information transmission.

CELL-SPECIFIC SYNAPTIC WIRING WITHIN THE HIPPOCAMPAL CA3 NETWORK

POSTER SESSION 06 - SECTION: MICROCIRCUITS AND NETWORK DYNAMICS

Jake Watson, Victor Vargas-Barroso, Rebecca Morse, Peter Jonas
Institute of Science and Technology Austria, Cellular Neuroscience, Klosterneuburg, Austria

Aims: The hippocampus is crucial for learning and memory, and the interconnected pyramidal neurons of its CA3 area appear uniquely configured for memory storage. However, while the overall information flow through the hippocampus has been long understood, little is known about individual cell wiring, which will dictate the rules of information processing. We aim to establish the microcircuit architecture of CA3, to understand its capabilities for memory formation. **Methods:** Using simultaneous multi-cellular patch-clamp recordings from up to 8 neurons in acute slices of mouse hippocampus, and post-hoc imaging of recorded cells, we determined the connectivity, synaptic properties, and arrangement of the CA3 network. **Results:** We recorded 49 synaptic connections between morphologically identified CA3 pyramidal neurons (Connection probability: 3.2 %), which show a non-random circuit architecture, containing sub-networks of highly interconnected cells. Unique subtypes of excitatory pyramidal neurons can be identified by functional and anatomical properties. We demonstrate that these subtypes have specific wiring rules, adding a further layer of complexity to the CA3 network. Connectivity between pyramidal neurons and local fast-spiking interneurons was more abundant than principal neuron interconnectivity (19 % connectivity, 48/250 confirmed connections), with unique synaptic properties that will differentially process excitatory activity in a frequency and spatially dependent manner. **Conclusions:** Our results shed new light on the microcircuit arrangement of the CA3 network. Non-random principal neuron connectivity and cellular heterogeneity may increase the processing capacity of the network, and suggest that distinct pyramidal subtypes could have specific roles in encoding life experiences within neuronal ensembles.

Neural activity in sensory cortex combines stimulus responses and ongoing activity, but it remains unclear whether they reflect the same underlying dynamics or separate processes. Here, using two-photon imaging of neuronal populations, we show that during wakefulness, the neuronal assemblies evoked by sounds in the auditory cortex and thalamus are specific to the stimulus and distinct from the assemblies observed in ongoing activity. In contrast, during isoflurane and ketamine-medetomidine anesthesia, evoked assemblies are indistinguishable from ongoing assemblies in the cortex. Using a visualization of thalamocortical fibers, we show that in all cases, the thalamocortical input remains distinct between spontaneous and sensory input, suggesting that the change of dynamics is essential of cortical origin. We also find that a strong remapping of sensory responses accompanies this dynamical state change produced by anesthesia. Together, these results show that the awake cortex engages dedicated neuronal assemblies in response to sensory inputs, which we suggest is a network correlate of sensory perception. ---

SELECTIVE INHIBITION OF EXCITATORY NEURONS ALTERS THE EMERGENT BURSTING DYNAMICS OF IN VITRO NEURAL NETWORKS

POSTER SESSION 06 - SECTION: MICROCIRCUITS AND NETWORK DYNAMICS

Janelle Shari Weir[1], Nicholas Christiansen[1], Axel Sandvig[1,2,3], Ioanna Sandvig[1]
[1]Norwegian University of Science and Technology (NTNU), Department Of Neuromedicine And Movement Science (inb), Trondheim, Norway, [2]Umeå University Hospital, Department Of Clinical Science, Division Of Neuroscience, Umeå, Sweden, [3]Umeå University Hospital, Department Of Community Medicine And Rehabilitation, Division Of Rehabilitation Medicine, Umeå, Sweden

Introduction At maturity, in vitro neural network activity is dominated by network bursts which play an important role in Hebbian plasticity for structural and functional connectivity. Network bursts are vital for neural information processing and are strong indicators of network computation. While bursting is the consequence of balanced excitatory-inhibitory interactions, the underlying functional mechanisms that facilitate this are still poorly understood. This is partly because we have limited knowledge of and access to the connections themselves. Hence, in our research we targeted specific synapses to investigate how plasticity rules may facilitate or hinder adaptive and maladaptive functional responses to network perturbation. *Materials and methods* In vitro neural networks of rat cortical neurons were transduced with adeno-associated viral vector encoding the inhibitory designer receptors exclusively activated by designer drugs (DREADDs) hM4Di protein, specifically targeted to excitatory neurons. The DREADDs were acutely activated by the novel synthetic ligand deschloroclozapine (DCZ), and network wide activity was recorded using microelectrode arrays (MEAs) before, during and after DCZ perturbation. *Preliminary results and analysis in progress* DCZ application to neural networks expressing DREADDs suppressed network bursting for up to 2hrs. Post washout, high frequency bursts reappeared by 2hrs, and were maintained for up to 24hrs. There was also evidence of increased synaptic strengths at several electrodes post washout, which were also maintained 24hrs later. *Conclusion* Global inhibition of excitatory neurons triggers homeostatic adaptive mechanisms by inducing rapid short-term facilitation. This study presents a novel method to investigate emergence in biological networks through manipulation of underlying network components.

GABAergic neurons shape the spatial and temporal organization of collective neuronal dynamics, thus playing a major role in both the developing and adult brain. However, it remains unclear how single GABAergic neurons causally impact the coordination of local neuronal assemblies *in vivo*. To address this question, we have developed a custom optical setup allowing to combine 2-photon calcium imaging and holographic optogenetic stimulation at single-cell resolution. We used soma-targeted ChroME and GtaCR1 opsins to excite and inhibit specific GABAergic cells with high spatiotemporal precision. We have applied this all-optical approach to the neonatal developing barrel cortex and the adult CA1 hippocampus in mice to shed light on the functional organization of developing and adult cortical networks.

DIFFERENT MODULATORY EFFECTS OF SEROTONIN AND 5-HT2A RECEPTOR SUBTYPE ACTIVATION ON SENSORIMOTOR AND MEDIAL PREFRONTAL BASAL GANGLIA CIRCUITS

POSTER SESSION 06 - SECTION: MICROCIRCUITS AND NETWORK DYNAMICS

Lise Guilhemsang[1,2,3], Amaia Gutierrez-Ceballos[3], Mario Antonazzo[3,4], Nicolas Mallet[1,2], Luisa Ugedo[3,4], Teresa Morera-Herreras[3,4]
[1]CNRS UMR 5293, Institut Des Maladies Neurodégénératives, Bordeaux, France, [2]Université de Bordeaux, Institut Des Maladies Neurodégénératives, Bordeaux, France, [3]Faculty of Medicine and Nursing, University of the Basque Country (UPV/EHU), Department Of Pharmacology, Leioa, Spain, [4]Autonomic and Movement Disorders, Neurodegenerative diseases Unit, Biocruces Health Research Institute, Barakaldo, Spain

The cortical information is transferred to the *substantia nigra pars reticulata* (SNr) through the sensorimotor (SM) and medial prefrontal (mPF) basal ganglia (BG) circuits that are implicated in motor and cognitive/motivational behaviours, respectively. All components of the BG circuits receive serotonergic (5-HT) innervation and express low/moderate densities of 5-HT2A receptors. This study investigated the effect of 5-HT on SM and mPF BG circuits and the specific contribution of 5-HT_{2A} receptors on their function. For that purpose, in vivo single-unit extracellular recordings of the lateral (included in the SM circuit) and medial (in the mPF circuit) SNr neurons along with simultaneous electrical stimulation of the motor and mPF cortex were performed in vehicle-, pCPA- and acute fluoxetine-treated anaesthetized rats, before, and after the administration of highly selective 5-HT_{2A} receptor agonist TCB-2. Results revealed a territory-dependent dissociation in 5-HT modulation over the SNr, as only the lateral SNr neuron activity was under the tonic inhibitory control of 5-HT. After fluoxetine, the cortico-SNr transmission through both SM and mPF circuits was altered. TCB-2 (50-200 µg/kg, i.v.) increased the medial SNr neuronal firing rate and had preferential action on the mPF circuit, inducing an imbalance between the functionality of trans-striatal pathways and favouring cortical information transfer via the direct pathway. Overall, these data contribute to a better understanding of the role of 5-HT in cortico-BG information processing and clarify the potential role that 5-HT_{2A} receptor-targeting drugs may have as a therapeutic in BG related disorders. Funding: GIU19/092, SAF2016-77758-R. L.G. is supported by UPV/EHU fellowship.

Simulating large-scale networks of neurons is an important approach when interpreting and synthesising different types of experimental data from healthy as well as from diseased brains. Here we focus on the striatum, the main input stage and largest nucleus of the basal ganglia. Basal ganglia are involved in motor learning, action-selection and reinforcement learning. Dysfunction in these areas lead to a variety of brain disorders like Parkinson's disease (PD), a neurodegenerative disorder that affects nerve cells. Understanding diseases related changes in the topology of striatal microcircuit can provide insights into striatal dynamics in both healthy and disease states. To characterise the topology of striatal network we used a nearly full-scale digital reconstruction of the mouse striatal microcircuitry (Hjorth, Kozlov et al., 2020). Neurodegeneration was modelled as progressive loss of the most distal fragments of the dendritic arbours. We are applying algebraic topology, in particular directed cliques (simplices), to investigate the local structural connectivity in striatum, and how structural features shape network dynamics. We show that progressive dendritic degeneration not only alters the global connection probabilities but also dramatically affects statistics of simplices particularly at the later PD stage. We found that interneurons despite being in minority can have a surprisingly large effect on the distribution of simplices. These results suggest that interneurons play a crucial role in shaping the striatal network structure as well as the dynamics.

UNDERSTANDING THE ROLE OF VIP+ INHIBITORY INTERNEURONS IN THE RETINA

POSTER SESSION 06 - SECTION: MICROCIRCUITS AND NETWORK DYNAMICS

Déborah Varro, Olivier Marre
Institut de la Vision, Ile De France, Paris, France

Understanding the role of inhibitory interneurons in shaping sensory computations is a major purpose in neuroscience. The inhibitory neurons expressing the vasoactive intestinal peptide (VIP+ cells) have been extensively studied in the cortex, but their exact role in the retina remains unclear. Anatomical studies suggest that these VIP+ amacrines cells have both inhibitory GABAergic synapses and gap-junctions [1-3]. However, the role of VIP+ amacrines cells in visual information processing in the retina is still unclear. In particular, we don't know how these two types of synapses can impact ganglion cells activity. Here we used optogenetic tools to stimulate VIP+ cells in two different ways: full-field stimulation and 2-photon holographic stimulation to target individual VIP+ cells with high resolution, while we recorded the impact of these stimulations on ganglion cells. We show that VIP+ amacrines cells can (i) activate ON ganglion cells, and (ii) suppress the activity of OFF ganglion cells, even over very long distances (up to 400µm). The activation of ON ganglion cells did not depend on GABAergic transmission, suggesting it results from gap junctions. Our results thus demonstrate that VIP+ cells differentially modulate different types of ganglion cells through different types of synapses. This suggests that these VIP+ cells could both (i) synchronize the response of ON ganglion cells populations, and (ii) participate in lateral inhibition to ganglion cells. Our results show that VIP+ differentially modulate different ganglion cell types and suggest that they play an important role in information processing in the retina.

Temporal theta activity in coalescence with slow-wave (TTA-SW) is one of the first neurobiomarkers of the neurodevelopment of perisylvian networks in the electroencephalography (EEG) of premature neonates. Dynamic changes in the microstructure and activity within neural networks are reflected in the EEG. Slow oscillation slope can reflect synaptic strength, and cross-frequency coupling (CFC), associated with several putative functions in adults, can reflect neural communication. Here, we investigated the evolution of CFC, in terms of SW theta phase-amplitude coupling (PAC), during the course of very early development between 25 and 32 wGA in 23 premature neonates. We used high-resolution EEG and dipole models as spatial filters to extract the source waveforms corresponding to TTA-SW. We also carried out nonlinear phase dependent correlation measurements to examine whether the characteristics of the SW slopes are associated with TTA-SW coupling. We show that neurodevelopment leads to temporal accumulation of the SW theta PAC towards the trough of SW. Steepness of the negative going slope of SW determined the degree of this coupling. Systematic modulation of SW-TTA CFC during development is a signature of the complex development of local cortico-cortical perisylvian networks and distant thalamo-cortical neural circuits driving this nested activity over the perisylvian networks.

SENSORIMOTOR BRAIN OSCILLATIONS IN HUMAN TODDLERS

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Helene Vitali[1,2], Claudio Campus[1], Valentina De Giorgis[3], Sabrina Signorni[3], Federica Morelli[3], Marco Fasce[3], Monica Gori[1]
[1]Italian Institute of Technology, Unit Of Visually Impaired People, Genova, Italy, [2]University of Genova, Dibris, Genova GE, Italy, [3]IRCCS Mondino Foundation, Unit Of Child Neuropsychiatrist, Pavia, Italy

Evidence, in the last decades, revealed a rhythmic modulation that involved sensorimotor processing. Natural behaviour relies on a dynamic interaction between multimodal sensorimotor loops.
To study these rhythms in the early years of life, we consider the non-nutritive sucking (NNS) behaviour in 17 typical infants/toddlers from 6 months to 3 years. While the pattern generating circuit of rhythmic oromotor activity is located in the brainstem, the quality of sucking behaviour is probably modulated by more cranial structures (e.g., cortico-spinal). So, we investigated how sensorimotor cortical rhythms (i.e. μ, β) are involved in this behaviour. Considering that a relationship between these EEG rhythms and movement speed has been previously reported, we hypothesized a proportional relationship between sucking frequency and sensorimotor oscillations during baseline, sucking or pre-sucking periods.
First, we performed a linear regression analysis between sucking frequency and spectral activity for μ1 [8-10Hz), μ2 [10-13Hz), β1 [14-21) and β2 [21-32) bands, measured as spectral power during baseline and sucking periods and their ratio. We found a correlation between sucking frequency with μ1 and β activity during baseline and sucking period, respectively. Then, we performed a time-frequency analysis which revealed the role of β1 activity in the pre-movement phase.
These results suggest the existence of different sensorimotor communication channels from birth and support the role of increased β rhythm in sensorimotor coordination. Acknowledgments: This research was partially supported by the European Research Council (PI Monica Gori; Grant agreement No. 948349).

Sensitive period for the plasticity of alpha activity in humans.
Visual experience is crucial for the development of neural processing. For example, alpha activity development is a vision-dependent mechanism. Indeed, studies report no alpha activity is present in blind adults. Nevertheless, studies have not investigated the developmental trajectory of this activity in infants and children with blindness. Here, we hypothesize that the difference in neural activity of blind compared to sighted subjects is: absent at birth, progressive with age, specifically occipital and linked to a gradual motor impairment. Therefore, we consider spectral power of resting-state EEG and its association with motor impairment indices, in blind subjects and in sighted controls between 0 and 11 years of age. Blind subjects show posterior alpha activity during the first three years of life, although weaker and slower maturing compared to sighted subjects. The first great differentiation between blind and sighted subjects occurs between 3 and 6 years of age. Starting in this period, reduced alpha activity increases the probability of motor impairment in blind subjects, likely because of impaired perception/interaction. These results show that visual experience mediates the neural mechanisms generating alpha oscillations during the first years of life, suggesting that it is a sensitive period for the plasticity of this process.

ASSESSING FUNCTIONAL NETWORKS DYNAMIC THROUGH HIGH-DENSITY LONGITUDINAL EEG RECORDINGS IN A NEW MOUSE MODEL OF EARLY ALZHEIMER'S DISEASE

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Matthieu Aguilera[1], Samy Castro[1], Chantal Mathis[1], Battaglia Demian[2,3], Romain Goutagny[1]
[1]Université de Strasbourg, CNRS, Laboratoire De Neurosciences Cognitives Et Adaptatives, Umr 7364, Strasbourg, France, [2]Aix-Marseille Université, Institute For Systems Neuroscience, Marseille, France, [3]University of Strasbourg, Usias, Strasbourg, France

Alzheimer's disease (AD) is a neurodegenerative pathology characterized by a progressive and irreversible deterioration of cognitive functions, especially memory. As first neuropathological hallmarks arise decades before first memory deficits, a critical challenge in current research on AD is to find a reliable and early marker of the disease. Recently, our team showed that a new AD mouse model, the humanized *App*$^{NL-F}$*xMAPT* double knock-in (dKI) model, could generate key information on the initial disease stage. Indeed, 4-month-old dKI mice present early recognition deficit in an object-place association task and a disorganization of medial temporal lobe internal communication. To better characterize network alteration in the early stage of the disease, we performed long-term high-density EEG recording starting at 2-month of age in dKI and control littermate mice. Using functional brain network dynamic analyses, our preliminary results tend to show differences between genotypes, even at this early disease stage. This prompted us to test the effect of a non-invasive visual stimulation on network functional connectivity. Indeed, recent studies have shown that 40 Hz gamma entrainment via visual stimulation protocol (vGENUS) can reduce AD impact by improving cognitive performance, while mechanisms underlying these effects remain unclear. We first showed that vGENUS effectively rescued memory deficits in young dKI mice in the object-place association task. Strikingly, the main effects on dynamic were not at the gamma entrainment frequency but on other brain rhythms. Our results will provide new insight into early network dynamic alterations and the beneficial effect of a non-invasive gamma visual stimulation in AD.

REVISITING NEURAL BASIS OF BELIEF UPDATING: P300, PUPIL DILATION AND BETA RHYTHM AS RELIABLE INDICES OF A UNITARY PROCESS

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Eleonora Malloggi[1], Silvia Animali[1], Angelo Gemignani[2], Enrica Bonanni[3], Francesco Fornai[1], Filippo Giorgi[1], Danilo Menicucci[2], Paola Binda[1]

AIMS A crucial step in making decisions is the updating of *a priori* beliefs based on current evidence. Belief updating is accompanied by three psychophysiological phenomena: P300, pupil dilation and electroencephalogram (EEG) power decrease, which some have linked to activity in norepinephrine-Locus Coeruleus system. However, these indices – albeit co-occurring – have been found uncorrelated across stimulus repetitions and participants, contradicting their alleged common origin. We aimed at re-examining this relationship employing a simple paradigm (3-stimulus oddball), thus avoiding confounding factors such as uncertainty and complexity; moreover, we aimed at overcoming these difficulties by separating out the impact of different factors (mainly, motor- vs. stimulus-related) on pupil and EEG responses. **METHODS** Event-related potentials (ERP) were derived from group-level (N=19) independent component analysis. Event-related spectral perturbations were computed *via* Short-Time Fourier Transform of those components. General Linear Model (GLM) was applied to identify EEG and pupil responses' predictors. **RESULTS** Besides confirming the co-occurrence of P300-like ERP, beta-band desynchronization and pupil dilation following target-oddball stimulus, we demonstrated a positive linear correlation among them (Pearson's correlation across participants, $r(19) = 0.60$, $p < 0.01$), which only emerged for stimulus-related component of pupil and EEG responses. **CONCLUSIONS** Our results highlight the complexity of pupil responses, which incorporate diverse factors that may confound the association of pupillometric and electrophysiological indices. However, once this complexity is appropriately modelled, phasic pupil dilation becomes predictive of P300-like ERP and beta-band suppression, supporting their inter-dependent nature, and proposing pupillometry as a useful tool for monitoring these physiological events.

INDIVIDUAL DIFFERENCES IN DOMINANT THETA-BAND FREQUENCY DURING ASSOCIATIVE MEMORY ENCODING

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Jovana Bjekić[1], Dunja Paunovic[1], Marko Živanović[2], Inga Griskova-Bulanova[3], Saša Filipović[1]
[1]University of Belgrade, Institute for Medical Research, Human Neuroscience, Belgrade, Serbia, [2]University of Belgrade, Faculty of Philosophy, Department Of Psychology, Belgrade, Serbia, [3]Vilnius University, Neurobiology And Biophysics, Vilnius, Lithuania

Individual differences in brain electrophysiologic activity have been recognized a long time ago. Electroencephalographic (EEG) indices such as individual alpha (IAF) and gamma (IGF) frequency have been extensively investigated as biomarkers of individual differences in baseline neurophysiological activity and in response to different stimuli. In contrast, individual differences in dominant theta frequency have received considerably less attention. Given that theta-band EEG activity underlies memory processes, better knowledge of its individual difference, besides improving understanding of the physiology of memory processes, is of foremost importance for personalization of future non-invasive neuromodulation treatment attempts for memory impairments (such as in dementia and other neurodegenerative disorders). The aim of this study was to explore individual differences in individual theta-band frequency (ITF) from a scalp EEG recorded during associative memory (AM) encoding. In a sample of 42 healthy young adults (age 20 – 35; 50% female) we extracted the frequencies (2-10 Hz, in 0.5 Hz steps) with the highest event-related spectral perturbation from 19 overlapping time windows and six centroparietal electrodes from the EEG recorded during successful encoding in the AM task. The ITF was defined as modal frequency (in the 4-8Hz range) in the given time x electrode matrix. The method showed 93% success rate and the range of variability of the extracted ITFs. We present and discuss individual differences in theta-band activity during AM encoding, together with ITF-extraction challenges.

40-HZ STIMULATION DURING NREM SLEEP INDUCES A SPECIFIC AUDITORY STEADY-STATE RESPONSE AND AN INCREASE IN THE SLEEP-SPINDLE POWER ASSOCIATED WITH UP AND DOWN CORTICAL STATES

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

David Henao-Herreño[1,2], Juan Nieto[1], Miguel Navarrete[1], Michel Le Van Quyen[3], Mario Valderrama[1]
[1]University of los Andes, Department Of Biomedical Engineering, Bogotá, Colombia, [2]CIRB, College de France, Neuroglial Interactions In Cerebral Physiopathology, Paris, France, [3]Laboratoire d'Imagerie Biomedicale, Connectivité Neurale Et Plasticité, Paris, France

Auditory Steady-State Response (ASSR) consists in a rhythmic brain activity resulting from sound stimuli presented periodically. This brain response is close to the stimulation frequency with a highest magnitude at 40 Hz. The ASSR has been evaluated as an assessment tool in different physiological conditions. For instance, it has been shown that ASSR is modulated by anesthesia and different vigilance states. In particular, it has been reported that ASSR decreases in NREM sleep compared to wake. Nevertheless, at a finer scale, it is not clear how this type of stimulation can induce brain changes when applied during up or down phases of slow oscillations (SO) characterizing NREM sleep. To assess this, we performed auditory stimulation during nights of 11 healthy subjects recorded with a scalp EEG system in a 10-20 configuration. Stimuli consisted of 40-Hz trains of white noise (400 ms). We classified stimulation events that fell around SO positive or negative peaks and for them we computed the 40-Hz ASSR through the Iter-Trial Coherence (ITC). We report a marked ITC with higher levels in frontal and central electrodes for both up and down states with no statistical difference between them. Furthermore, when compared to sham events, stimulation during both positive and negative peaks induced a strong significant enhancement ($p < 0.05$) of sleep spindle power for the majority of electrodes around 1 sec after the stimulus onset. Taken together, our results suggest that 40-Hz auditory stimulation can be an efficient way for inducing specif brain responses during sleep.

DATA-DRIVEN EEG THETA AND ALPHA COMPONENTS ARE ASSOCIATED WITH SUBJECTIVE EXPERIENCE DURING RESTING STATE

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Povilas Tarailis[1], Inga Griskova-Bulanova[2]
[1]Vilnius University, Biosciences Institute, Vilnius, Lithuania, [2]Vilnius University, Neurobiology And Biophysics, Vilnius, Lithuania

The resting-state paradigm is frequently applied in EEG research; however, it is associated with the inability to control participant's thoughts. To quantify subjects' subjective experiences at rest, the Amsterdam Resting-State Questionnaire (ARSQ) was introduced covering ten dimensions of mind wandering. We aimed to estimate associations between subjective experiences and data-driven EEG components extracted using frequency Principal Components Analysis (f-PCA). 5 minutes of resting-state EEG data of 226 subjects were used to evaluate data-driven EEG components extracted with f-PCA. The Bayesian correlation approach was implemented to assess associations between ARSQ domains assessed after resting and f-PCA outcomes. Three alpha components, one beta, one theta, and one delta component were identified corresponding to previous reports on the resting state EEG. Only frontal midline theta component peaking at 5.5 Hz and alpha component peaking at 9 Hz were positively associated with individual ratings of Sleepiness ($r=0.198$, $BF10 =7.115$) and Comfort ($r=0.200$, $BF10 =7.676$). No other correlations emerged. The inverse model of sLORETA for the theta component showed the main activation of the voxels at limbic lobe and anterior cingulate. The correlations observed between theta component and Sleepiness and alpha component and Comfort are in line with previously reported associations on EEG and fMRI signals, pointing to the relevance of assessments of spontaneous thoughts occurring during the resting state.

ABNORMAL PATTERNS OF SLEEP AND WAKING BEHAVIORS ARE ACCOMPANIED BY INCREASED SLOW GAMMA POWER IN AN ANK3 MOUSE MODEL OF EPILEPSY-MOOD DISORDER COMORBIDITY

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Nicholas Riveira, Juan Villacres, Sohmee Kim, Laura Colgin, Angel Lopez
University of Texas at Austin, Neuroscience, Austin, United States of America

The ANK3 gene is a leading bipolar disorder candidate gene in humans. Previous studies showed that a bipolar disorder (BD)-associated variant of ANK3 (ANK3-1b) leads to increased firing threshold and diminished action potential dynamic range of parvalbumin (PV) interneurons and absence epilepsy in mice, thus providing a potential mechanistic link between epilepsy and BD. To better understand the impact of PV interneurons on network activity and behavior in these mice, we examined spectral correlates of behaviors seen in *Ank3-1b* knockout (KO) mice during overnight home-cage activity using paired video-EEG recordings. PV interneuron dysfunction and aberrant gamma rhythms have been implicated in BD. Also, the fast-spiking properties of PV interneurons make them important for generating and modulating high frequency gamma oscillations. Thus, we anticipated changes in the power of EEG signals in the gamma frequency range (> 25 Hz) during behaviors related to BD symptoms seen in human patients such as changes in sleep and activity levels. *Ank3-1b* KO mice exhibited an overall increase in slow gamma (~25-45 Hz) power compared to controls, and slow gamma power correlated with seizure phenotype severity across behaviors. Notably, during sleep, increased slow gamma power co-occurred with decreases in time spent in the rapid eye movement (REM) phase. We also identified a repetitive behaviors phenotype in *Ank3-1b* KO mice that co-occurred with increased slow gamma power. These results further support the association of *Ank3-1b* with BD and suggest modulation of gamma oscillations as a potential therapeutic target.

Dose-dependent changes in the locomotor responses to methamphetamine in BALB/c mice: low doses induce hypolocomotion.
The overall goal of the present study was to determine the effects of different doses of (+)-methamphetamine (meth) on locomotor activity of Balb/C mice. Four experiments were designed to test a wide range of meth doses in BALB/c female mice. In Experiment 1, we examined locomotor activity induced by an acute administration of low doses of meth (0.01 and 0.03mg/kg) in a 90-min session. Experiment 2 was conducted to test higher meth doses (0.3-10mg/kg). In Experiment 3, separate sets of mice were pre-treated with various meth doses once or twice (one injection/week) prior to a locomotor challenge with a low meth dose. Finally, in Experiment 4, we tested whether locomotor activation would be affected by pretreatment with a low or moderate dose of meth one month prior to the low meth dose challenge. Results show that low doses of meth induce hypolocomotion whereas moderate to high doses induce hyperlocomotion. Prior exposure to either one moderate or high dose of meth or to two, low doses of meth attenuated the hypolocomotor effect of a low meth dose one week later. This effect was also attenuated in mice tested one month after administration of a moderate meth dose. These results show that low and high doses of meth can have opposing effects on locomotor activity. Further, prior exposure to the drug leads to tolerance, rather than sensitization, of the hypolocomotor response to low meth doses.

Ankyrin-G isoform imbalance and interneuronopathy link epilepsy and bipolar disorder.
ANK3, encoding the adaptor protein Ankyrin-G (AnkG), has been implicated in bipolar disorder by genome-wide association studies. ANK3 has multiple alternative first exons, and a bipolar disorder-associated ANK3 variant has been shown to reduce the expression of exon 1b. Here we identify mechanisms through which reduced ANK3 exon 1b isoform expression disrupts neuronal excitation-inhibition balance. We find that parvalbumin (PV) interneurons and principal cells differentially express ANK3 first exon subtypes. PV interneurons express only isoforms containing exon 1b, whereas excitatory principal cells express exon 1e alone or both 1e and 1b. In transgenic mice deficient for exon 1b, PV interneurons lack voltage-gated sodium channels at their axonal initial segments and have increased firing thresholds and diminished action potential dynamic range. These mice exhibit an Ank3 gene dosage-dependent phenotype including behavior changes modeling bipolar disorder, epilepsy and sudden death. Thus ANK3's important association with human bipolar susceptibility may arise from imbalance between AnkG function in interneurons and principal cells and resultant excessive circuit sensitivity and output. AnkG isoform imbalance is a novel molecular endophenotype and potential therapeutic target.

STUDYING GAMMA OSCILLATIONS AND CONSCIOUSNESS DURING SLEEP USING SSVEPS

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Laura Hainke[1], Sebastian Herberger[2], Paul Taylor[1], James Dowsett[1]
[1]Ludwig-Maximilians-University, Psychology, Munich, Germany, [2]Mentalab, Mentalab Gmbh, Munich, Germany

Consciousness has been the focus of many scientific works over the past decades, but the debate about how to best study or define it is nowhere near settled. Brain oscillations in Gamma range (> 30 Hz) were highlighted in the literature devoted to Neural Correlates of Consciousness as a potentially relevant biomarker, usually assessed through EEG. Here, we focus on Gamma-range oscillations during wakefulness and sleep, where REM and NREM stages represent different states of (un)consciousness. Steady-State Visually Evoked Potentials (SSVEPs) have proven to be an effective way to study brain oscillations, even during sleep (Sharon & Nir, 2018). In this study, we demonstrate the feasibility of recording SSVEPs in the Gamma range during different sleep stages. A fully mobile setup is employed, including a custom-made sleep mask with LEDs to induce periodic visual flicker, along with the mobile EEG system Mentalab Explore. This novel method allows for a more naturalistic and effective study of oscillations during sleep, while ensuring a greatly improved Signal-To-Noise Ratio of the EEG data. Further studies based on this technique will be applied to larger samples for validation, as well as clinical populations with Disorders of Consciousness.

MATHEMATICAL SIMULATION ENLIGHTENMENT AND EXPERIMENTAL IMPROVEMENT OF TDCS IN A MODEL OF PSYCHOTIC TRANSITION: A TRANSLATIONAL STUDY

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Joséphine Riedinger[1,2], Axel Hutt[1], Didier Pinault[2]
[1]INRIA Nancy Grand Est, Ihu - Mimesis, Strasbourg, France, [2]Université de Strasbourg, Crbs, Inserm U1114, Strasbourg, France

The transcranial Direct Current Stimulation (tDCS) is a non-invasive promising neuromodulation approach to treat psychotic disorders, like schizophrenia. During the psychotic transition, symptoms are associated with disturbance of neuronal oscillations (oscillopathies), notably in the Cortico-Thalamo-Cortical (CTC) system. A state that can be mimicked in mammals by injection of a psychotomimetic dose of the NMDA receptor antagonist ketamine. It was demonstrated in rats that a unilateral fronto-parietal anodal tDCS can reduced ketamine-induced oscillopathies, with a differential efficiency on hemispheres. Our pre-clinical translational study proposes to bilaterally normalize ketamine-induced oscillopathies and to provide insights about CTC response to tDCS. To this aim, stimulation parameters are experimentally optimized and a mathematical model of the CTC neuronal populations was designed. In sedated rats, while recording fronto-parietal electroencephalogram, an acute ketamine administration was performed (2.5 mg/kg), followed by anodal or cathodal inter-hemispheric tDCS (from ± 0.5 to ± 2 mA). Parallelly, reproducing experimental conditions in numerical simulations brought information on subcortical states. Experimental results reveal that anodic and cathodic inter-hemispheric stimulation has a coherent spatio-temporal effect on both hemispheres, and are able to damped the peak effect of ketamine. Also, the +1 mA stimulation normalize oscillopathies 40 minutes after ketamine injection (versus 80-90 minutes in the sham condition). Moreover, numerical simulations highlighted the importance of delta rhythm synchronicity in psychosis and showed that anodal tDCS globally increase functional connectivity in the CTC circuit. These results draw the contours of an innovative preventive treatment by neuromodulation in psychiatry and lighten tDCS influence on networks.

EFFECTIVE CONNECTIVITY ANALYSIS BASED ON COUPLED NEURAL MASS MODEL FOR TMS-EEG DATA

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Yuki Sasaoka[1], Keiichi Kitajo[2], Katsunori Kitano[3]
[1]Ritsumeikan University, Graduate School Of Informatics, Kusatsu, Japan, [2]National Institute for Physiological Sciences, Division Of Neural Dynamics, Okazaki, Japan, [3]Ritsumeikan University, Information Science And Engineering, Kusatsu, Japan

Functional or effective connectivity analysis of the whole brain activity based on non-invasive recording has been gaining importance for understanding the mechanisms of interactions between brain regions during cognitive functions. While most of the analysis methods proposed so far are data-driven (model-free) ones, the methods utilizing the dynamical characteristics of neural activity might arrow us to understand the mechanism of interaction between brain regions more deeply. To this end, we employed coupled neural mass model to EEG data as the interregional brain dynamics to mathematically describe the measured neural activity. We derived parameters of the model such that it could reproduce characteristics of the measured data such as in the frequency- and temporal domains by minimizing difference in power spectrum density distribution and permutation patterns of time-series distribution between measured and simulated activity. In the present study, the proposed method was applied to EEG data with Transcranial Magnetic Stimulation (TMS) to see if it could detect TMS effects as a change in the parameter of inter-regional connection. As a result, (i) it was implicated that the proposed method successfully estimated model parameters that could reproduced the characteristics of EEG activity, (ii) the proposed method could detect TMS effect particularly in the regions near the TMS target, (iii) the parameter estimation was robust between different sessions conducted for identical subjects.

TITLE : INFLUENCE OF BEHAVIORAL ACTIVITY LEVEL ON THE OCCURRENCE OF ABSENCE EPILEPTIC SEIZURES IN GAERS RATS

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Hieu Tran[1], Réda El Mahzoum[2], Agnès Bonnot[1], Ivan Cohen[1]
[1]Sorbonne Université- UMR8246, Neurosciences Paris Seine, paris, France, [2]Sorbonne Université- UMR8246, Neurosciences Paris Seine, Paris, France

Aim : Absence epilepsy is a generalized epilepsy characterized by sudden and brief loss of consciousness and affecting mostly children and teenagers, due to a large amout of remittance after puberty. Predicting the probability of the occurrence of an absence seizure may not only help to prevent seizures, but also to better understand the mechanism that triggers them. In this study, we investigated the interraction between two behavioral states (active and resting) and the occurrence of seizures. **Method :** Electroencephalographic recordings were performed continuously over a long period (5-7 days) to determine the occurrence of seizures in the Genetic Absence Epileptic Rat of Strasbourg (GAERS) model. In addition, the electrooculography, neck electromyography and head acceleration signals allowed the identification of active and resting behavioral states. **Result :** We found that seizures occur more often around the transition between periods of activity and rest, especially when the animal moves from an active to a resting state. Furthermore, in the epileptic rats, the active phase lasted longer on average than in controls. **Conclusions :** These results suggests that transition states, by acting on the level of excitability of the neuronal networks, could be a determining factor in the seizure triggering process. Furthermore, longer active phase in epileptic rats could participate in the development of commorbidities like increased anxiety and learning deficits.

THE SPECTRAL AND FRACTAL NEURODYNAMICAL FEATURES AS A SIGNATURE OF CORTICAL AREAS: AN INSIGHT FROM MONTREAL NEUROLOGICAL INSTITUTE INTRACRANIAL SEEG

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Karolina Armonaite[1], Livio Conti[2,3], Franca Tecchio[4]
[1]Uninettuno University, Faculty Of Psychology, Rome, Italy, [2]Uninettuno University, Faculty Of Engineering, Rome, Italy, [3]INFN - Istituto Nazionale di Fisica Nucleare, Sezione Roma Tor Vergata, Rome, Italy, [4]Consiglio Nazionale delle Ricerche, Laboratory Of Electrophysiology For Translational Neuroscience, Institute Of Cognitive Sciences And Technologies, Rome, Italy

Measuring power spectral density (PSD) and Higuchi fractal dimension (HFD) of intracranial sEEG, from Montreal Neurological Institute, we investigate the neurodynamics of 21 subjects in primary motor (M1), somatosensory (S1), and auditory (A1) cortices across wakefulness, N2, N3, and REM sleep stages. We aim to assess if the spectral and fractal features of the local ongoing electrical activity allow distinguishing cortical areas across different states and to evaluate whether a measure of fractal properties, typical of complex systems, catch physiological features possibly missed by linear spectral analyses. We observed specific spectral properties in wakefulness, where the prevailing frequencies above beta band were in M1, the alpha band waves were prevalent in S1, and the delta in A1. We also detected a transition from higher to lower frequencies depending on the sleep depth in the three regions of interest. On the contrary, HFD showed the ability to describe the sEEG complexity by being constantly higher in M1 than in S1, which in turn is higher than A1, steadily through all states of wakefulness and sleep. The core result of this study is to have highlighted the existence of typical features in distinct cortical parcels and that these properties maintain even during sleep. Moreover, this study confirmed our hypothesis that the measures of complexity (such as HDF) can detect the specificities of the ongoing electrical activity better than the linear ones. A distinction of neurodynamical properties of specific primary cortices supports the efforts in cortical parcelling based on their local electrical activity.

Neuronal Electrical Ongoing Activity as Cortical Areas Signature: An Insight from MNI Intracerebral Recording Atlas.
The time course of the neuronal activity in the brain network, the neurodynamics, reflects the structure and functionality of the generating neuronal pools. Here, using the intracranial stereo-electroencephalographic (sEEG) recordings of the public Montreal Neurological Institute (MNI) atlas, we investigated the neurodynamics of primary motor (M1), somatosensory (S1) and auditory (A1) cortices measuring power spectral densities (PSD) and Higuchi fractal dimension (HFD) in the same subject (M1 vs. S1 in 16 subjects, M1 vs. A1 in 9, S1 vs. A1 in 6). We observed specific spectral features in M1, which prevailed above beta band, S1 in the alpha band, and A1 in the delta band. M1 HFD was higher than S1, both higher than A1. A clear distinction of neurodynamics properties of specific primary cortices supports the efforts in cortical parceling based on this expression of the local cytoarchitecture and connectivity. In this perspective, we selected within the MNI intracortical database a first set of primary motor, somatosensory and auditory cortices' representatives to query in recognizing ongoing patterns of neuronal communication. Potential clinical impact stands primarily in exploiting such exchange patterns to enhance the efficacy of neuromodulation intervention to cure symptoms secondary to neuronal activity unbalances.

INTRINSIC ORGANIZATION OF HIPPOCAMPAL OSCILLATIONS

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Brijesh Modi[1], Matteo Guardamagna[2], Federico Stella[2], Marilena Griguoli[3], Enrico Cherubini[1], Francesco Battaglia[2]
[1]European Brain Reseach Institute, Fondazione Rita Levi Montalcini, Rome, Italy, [2]Radboud University, Donders Institute, Nijmegen, Netherlands, [3]CNR, Institute Of Molecular Biology And Pathology, Rome, Italy

Neuronal oscillations, a hallmark of mammalian brain, well preserved during evolution, enable synchronization of neural activity within and across brain regions, thus promoting the precise temporal coordination of neural processes underlying high cognitive functions. Oscillatory activity, occurring simultaneously in a given area at any given time, is thought to represent a physiological unit of a given brain state. Here, an analytical method has been developed to investigate how simultaneously occurring network oscillations, occurring at different frequencies, contribute to build up the network state space in the CA1 region of the hippocampus. To this aim, mice were chronically implanted with tetrodes/silicon probes during sleep and exploration of an arena during wakefulness. Power signals in distinct frequency bands ranging from 0.5 to 200 Hz, were extracted from local field potentials in *stratum pyramidale, radiatum and lacunosum moleculare* and were used to construct the state space of oscillations. The UMAP algorithm was employed to project the multi-dimensional (D) state space into 2D projection. With this approach, significant differences in the organization of oscillatory activity were detected among wake, REM and non-REM sleep. In addition, this method allowed unveiling state dependent coupling among different oscillations as well as alterations in state transitions after exploration of a novel arena suggesting the existence of a plasticity process at the network level. Finally, this approach allowed to study the firing activity of different neurons in the context of different brain states and their modulation by distinct network oscillations and *vice versa.*

Possible Implication of the CA2 Hippocampal Circuit in Social Cognition Deficits Observed in the Neuroligin 3 Knock-Out Mouse, a Non-Syndromic Animal Model of Autism.
Autism spectrum disorders (ASDs) comprise a heterogeneous group of neuro-developmental abnormalities with a strong genetic component, characterized by deficits in verbal and non-verbal communication, impaired social interactions, and stereotyped behaviors. In a small percentage of cases, ASDs are associated with alterations of genes involved in synaptic function. Among these, relatively frequent are mutations/deletions of genes encoding for neuroligins (NLGs). NLGs are postsynaptic adhesion molecules that, interacting with their presynaptic partners neurexins, ensure the cross talk between pre- and postsynaptic specializations and synaptic stabilization, a condition needed for maintaining a proper excitatory/inhibitory balance within local neuronal circuits. We have focused on mice lacking NLG3 (NLG3 knock-out mice), animal models of a non-syndromic form of autism, which exhibit deficits in social behavior reminiscent of those found in ASDs. Among different brain areas involved in social cognition, the CA2 region of the hippocampus has recently emerged as a central structure for social memory processing. Here, recordings from anesthetized animals and recordings from hippocampal slices have been used to assess the dynamics of neuronal signaling in the CA2 hippocampal area. experiments from NLG3-deficient mice revealed a selective impairment of spike-related slow wave activity in the CA2 area and a significant reduction in oscillatory activity in the theta and gamma frequencies range in both CA2 and CA3 regions of the hippocampus. These network effects were associated with an increased neuronal excitability in the CA2 hippocampal area. recordings from CA2 principal cells in slices obtained from NLG3 knock-out animals unveiled a strong excitatory/inhibitory imbalance in this region accompanied by a strong reduction of perisomatic inhibition mediated by CCK-containing GABAergic interneurons. These data clearly suggest that the selective alterations in network dynamics and GABAergic signaling observed in the CA2 hippocampal region of NLG3 knock-out mice may account for deficits in social memory reminiscent of those observed in autistic patients.

Microglia control glutamatergic synapses in the adult mouse hippocampus.

Microglia cells are active players in regulating synaptic development and plasticity in the brain. However, how they influence the normal functioning of synapses is largely unknown. In this study, we characterized the effects of pharmacological microglia depletion, achieved by administration of PLX5622, on hippocampal CA3-CA1 synapses of adult wild type mice. Following microglial depletion, we observed a reduction of spontaneous and evoked glutamatergic activity associated with a decrease of dendritic spine density. We also observed the appearance of immature synaptic features and higher levels of plasticity. Microglia depleted mice showed a deficit in the acquisition of the Novel Object Recognition task. These events were accompanied by hippocampal astrogliosis, although in the absence ofneuroinflammatory condition. PLX-induced synaptic changes were absent in Cx3cr1 mice, highlighting the role of CX3CL1/CX3CR1 axis in microglia control of synaptic functioning. Remarkably, microglia repopulation after PLX5622 withdrawal was associated with the recovery of hippocampal synapses and learning functions. Altogether, these data demonstrate that microglia contribute to normal synaptic functioning in the adult brain and that their removal induces reversible changes in organization and activity of glutamatergic synapses.

DO SPONTANEOUS ALPHA OSCILLATIONS PREDICT SUBJECTIVE TIME DURING RESTING-STATE?

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Leila Azizi[1], Ignacio Polti[2,3], Virginie Van Wassenhove[1]
[1]CEA, INSERM, CNRS, Université Paris-Saclay, Cognitive Neuroimaging Unit, Neurospin, Cea, Inserm, Cnrs, Université Paris-saclay, 91191 Gif/yvette, France., Gif/Yvete, France, [2]NTNU, Kavli Institu For Systems Neuroscience,, Trondheim, Norway, [3]Max Planck Institute for Human Cognitive and Brain Sciences, Department Of Psychology, Leipzig, Germany

In time perception research, alpha rhythms were seminally proposed to embody the internal clock, but most studies attempting to link time estimates with spontaneous alpha dynamics have failed to provide conclusive evidence. Here, we revisit this hypothesis with a new approach. We recorded 63 human participants for a few minutes of resting-state with magnetoencephalography (MEG). Before the MEG recording, participants were not instructed to attend to the passage of time; after the MEG recording, they were asked to estimate how long the recording lasted. Participants retrospectively underestimated the duration they spent in resting-state. We found that the power of alpha rhythms (7-14 Hz) during resting-state linearly predicted participants' retrospective time estimates and specifically, the duration of alpha bursts (more than their amplitude) was a predictor of retrospective duration. As a control condition, a subgroup of 25 participants from the same pool of participants performed a prospective duration estimation task in which they knew ahead of the MEG recording they would have to attend to the passage of time. In this case no relation between the alpha rhythm and prospective time estimates was found. Moreover, at the time scale of minutes, we found no evidence that alpha peak frequency would be linked to retrospective or prospective timing. In the absence of attention to time and task demands, alpha bursts may embody discrete states of awareness like timestamps in our episodic landscape, from which accurate duration estimates can be recollected retrospectively. **Keywords** : episodic timing, retrospective, prospective, time perception, alpha bursts, M/EEG

PATTERNS OF PREFRONTAL-HIPPOCAMPAL CIRCUIT DEVELOPMENT IN JUVENILE MICE IN HEALTH AND A GENETIC RISK MODEL FOR SCHIZOPHRENIA

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Marilena Hnida, Jastyn Pöpplau, Ileana Hanganu-Opatz
Center for Molecular Neurobiology Hamburg, University Medical Center Hamburg-Eppendorf, Institute For Developmental Neurophysiology, Hamburg, Germany

Higher cognitive abilities, such as the capacity to hold information temporarily, defined as working-memory (WM), critically depend on prefrontal-hippocampal coupling. On the flip side, poor cognitive performance in neuropsychiatric disorders results from prefrontal-hippocampal miswiring. We previously showed that the communication between prefrontal cortex (PFC) and hippocampus (HP) emerges early in life and that neonatal dysfunction of both areas is present long before the cognitive deficits. However, it is still unknown, how developing prefrontal-hippocampal circuits underlie the maturation of WM at juvenile age and whether network dysfunction towards late development predicts poorer WM performance in disease. To fill this knowledge gap, we monitor the patterns of neuronal and network activity in the PFC and HP throughout adolescent development (postnatal day (P) 16-60) in control and Df16(A)$^{+/-}$ mice that model human 22q11.2 microdeletions of neuropsychiatric disorders. Both groups are investigated during resting state (i.e. no task) and WM testing. During resting state, prefrontal gamma oscillations and firing in control mice progressively augment in their frequency and amplitude peaking around P30, and decrease afterwards. These developmental gamma features are impaired in the Df16(A)$^{+/-}$ model. After a transient decrease at around P16-20, theta band coupling between PFC and HP stabilizes at a high level along the juvenile development, being accompanied by an increase in WM performance. The prefrontal-hippocampal coupling is lower in Df16(A)$^{+/-}$ mice and disrupted during WM task. Thus, juvenile age represents a developmental time window of critical relevance for prefrontal-hippocampal function and cognitive maturation in health and disease.

CORTICAL STATES DYNAMICS ACROSS THE MOUSE SLEEP WAKE CYCLE

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Flore Boscher
CRNL, Sleep, Bron, France

Cortical states dynamics across the mouse sleep wake cycle The close resemblance between the electroencephalogram (EEG) observed during paradoxical sleep (or Rapid Eye Movement sleep, REM) and the EEG patterns observed during the fundamentally different cognitive state of wakefulness led Llinas and Paré (1991) to propose that REM and wakefulness are equivalent functional states, although the weight given to sensory inputs differs. The aim of this project is to investigate how the mouse whiskers sensory inputs are encoded in the cortex throughout the sleep-wake cycle. We performed local field potential (LFP) recordings in the primary somatosensory (S1) and motor (M1) cortices, combined with EEG and electromyogram recordings and the video-tracking of whisker movements. Our results reveal an acceleration of EEG Theta oscillations in REM concomitant with whisker movements. At the level of S1-LFP, we observe during REM the presence of spindle oscillations, typically associated with slow-wave-sleep, but exclusively outside whisking periods. The spectral analysis of S1-LFP also exhibits a significant decrease of the 2-5Hz power range during whisker movements, in both wakefulness and REM. This modulation in 2-5Hz power associated with whisker movements is also observed in M1-LFP and on the EEG but only in wakefulness. Therefore, our data show a modulation of the cortical activity associated with whisker movements that is restricted to S1 in REM, and which might underlie a more local sensory processing as well as a decrease in cortico-cortical integration during this state.

PROPAGATING SPIKING ACTIVITY IN THE THALAMUS OF ANESTHETIZED RODENTS

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Csaba Horváth[1,2], Mária Steinbach[3], István Ulbert[1,3], Richárd Fiáth[1,3]
[1]Research Centre for Natural Sciences, Institute Of Cognitive Neuroscience And Psychology, Budapest, Hungary, [2]Semmelweis University, János Szentágothai Doctoral School Of Neurosciences, Budapest, Hungary, [3]Pázmány Péter Catholic University, Faculty Of Information Technology And Bionics, Budapest, Hungary

Propagating waves are involved in many aspects of brain functions such as neural computations in sensory and motor systems, or regulation of synaptic events; both during wakefulness and sleep. The subject of our research was the thalamus, which plays an essential role in generating both slow oscillations and sleep spindles. Previous research on the propagation of thalamic oscillations is mostly based on in vitro studies. However, the application of multi-shank and high-density silicon-based probes now allows us to investigate the firing patterns of neuronal populations both at high spatial and temporal resolution in vivo. Using these techniques, we investigated whether propagating waves can be recorded in the thalamus of anesthetized mice and rats. We used NeuroNexus multi-shank probes (having 64 or 128 recording sites) and high-density Neuropixels probes with 384 channels (selectable from 960 sites) to record spontaneous activity patterns from several nuclei of the thalamus simultaneously. Our preliminary results indicate that, for both species, propagating firing activity appears principally in higher-order thalamic nuclei (e.g., Po or LDVL). Furthermore, we found that spatiotemporal patterns of these traveling neuronal waves are highly dependent on the actual brain state. Propagating patterns of sleep spindles were mainly observed in first-order nuclei (e.g., in the VPM). Our findings also suggest that the appearance and properties of propagating neuronal activity observed in the thalamus in vivo might be significantly influenced by a number of factors including the depth of anesthesia, the type of anesthetic used, or the degree of synchronization of the thalamocortical network.

Dataset of cortical activity recorded with high spatial resolution from anesthetized rats.
Publicly available neural recordings obtained with high spatial resolution are scarce. Here, we present an electrophysiological dataset recorded from the neocortex of twenty rats anesthetized with ketamine/xylazine. The wideband, spontaneous recordings were acquired with a single-shank silicon-based probe having 128 densely-packed recording sites arranged in a 32 × 4 array. The dataset contains the activity of a total of 7126 sorted single units extracted from all layers of the cortex. Here, we share raw neural recordings, as well as spike times, extracellular spike waveforms and several properties of units packaged in a standardized electrophysiological data format. For technical validation of our dataset, we provide the distributions of derived single unit properties along with various spike sorting quality metrics. This large collection of in vivo data enables the investigation of the high-resolution electrical footprint of cortical neurons which in turn may aid their electrophysiology-based classification. Furthermore, the dataset might be used to study the laminar-specific neuronal activity during slow oscillation, a brain rhythm strongly involved in neural mechanisms underlying memory consolidation and sleep.

WHAT IS A BURST? TRANSIENT BETA BAND PHENOMENA IN SINGLE-TRIAL FRONTAL OSCILLATORY DYNAMICS HAVE DIFFERENT PROPERTIES DEPENDING ON THE BURST DETECTION METHOD USED.

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Zachary Langford[1], Emmanuel Procyk[2], Charlie Wilson[1]
[1]SBRI Inserm U1208, Neurobiology Of Executive Functions, Bron, France, [2]INSERM U1208, Stem-cells And Brain Research Institute, Bron, France

Motor and cognitive processes are reliably accompanied by trial-averaged differences in the beta band (12-35 Hz) localized to sensorimotor and frontal areas. Yet, this act of averaging appears to do a disservice to the true underlying dynamic. It is increasingly clear that non-sustained transient 'burst-like' rhythms are the predominant feature in the beta band. Whilst the analysis of the properties of bursts of oscillation in cortex is an increasing feature of the field, the methods used to detect and identify those bursts shows significant variation, and as such the definition of what constitutes a burst must vary as well. Here we systematically compare published burst detection methods – power threshold and cycle-by-cycle approaches - on simulated and real neural data. First, we simulate realistic neural data with bursts that have different distributions of burst characteristics and evaluate how each method classifies bursts. Second, we use each method to detail the characteristics of the bursts recovered in real data from mouse and macaque recordings (local field potential and ECoG); and detail the differences of burst characteristics recovered by each method. Our analyses show that phenomena considered to be "beta bursts" by different detection methods have strikingly different oscillatory and temporal properties. They may have very different functional implications and should not all be grouped together. These results have methodological implications for the field, but more fundamentally they reveal multiple phenomena in neural data that could be considered "bursts", with different properties.

Neuronal oscillations are a prominent feature of motor cortical local field potentials (LFPs) and abnormalities in oscillatory activity have been linked to several disorders. Theta-modulated gamma frequency pulses of alternating current stimulation modulate human motor learning, however, it is unclear how these frequencies modulate motor cortical activity at the microcircuit level. Here, we aimed to develop a method of bidirectionally modulating theta and gamma coupled oscillations in the motor cortex using closed-loop optogenetic stimulation of parvalbumin-expressing (PV) interneurons. Motor cortical LFPs and single units were recorded in PV-Cre mice in which PV-interneurons were transfected with Channelrhodopsin-2 allowing reliable modulation of ongoing spiking activity with blue light. Using our recently developed phase-tracking system, pulses of blue-light were delivered at four target phases of the ongoing theta oscillation in the motor cortical LFP. Light was delivered over a quarter of the theta cycle, either as a continuous pulse or a burst of three pulses at gamma frequency. Both the continuous pulse and gamma frequency stimulation modulated theta power in a phase-dependent manner, with stimulation targeted to the ascending and descending phases suppressing and amplifying theta power respectively. This study demonstrates that theta power can be modulated using phase-dependent closed-loop optogenetic stimulation of PV-expressing interneurons and that this can be achieved using gamma frequency stimulation. These methods can be used to uncover the mechanism through which oscillatory manipulations modulate cortical activity and aid their future development.

MICROGLIA-MEDIATED REORGANIZATION OF ADOLESCENT PREFRONTAL CIRCUITRY UNDERLIES ADULT COGNITIVE ABILITIES

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Jastyn Pöpplau, Timo Schwarze, Ileana Hanganu-Opatz
University Medical Center Hamburg-Eppendorf, Institute Of Developmental Neurophysiology, Hamburg, Germany

Brain development is not a linear process. The relevance of critical time windows of development has been extensively documented for sensory systems, yet it is still a matter of debate, whether similar processes occur in brain areas accounting for cognitive behavior, such as the prefrontal cortex. Our recent data demonstrate that during neonatal development, perturbation of prefrontal activity dramatically disrupts adult network function and cognition. However, the protracted timeline of the maturation of higher-order cognitive abilities, leads to the hypothesis that critical windows for adult prefrontal functioning extend to the adolescent period. To prove this hypothesis, we combine chronic extracellular recordings and optogenetic manipulations with in-depth morphological and behavioral assessments of mice from early pre-juvenile age until adulthood. We show that neuronal firing complexity, oscillatory phase-amplitude synchrony, and excitation/inhibition ratio of prefrontal network activity increase almost linearly with age. In contrast, oscillatory gamma power and firing rates of regular spiking neurons deviate from a linear transition and peak during early adolescence. The timeline of these functional changes relates to a temporal augmentation of dendritic complexity of pyramidal neurons and increased pruning of excitatory postsynaptic compartments of these neurons by microglia cells. Pharmacological inactivation of microglia cells during adolescence but not adult age leads to a lasting increase in broadband gamma power and shifts the excitation/inhibition ratio towards excitation, causing ultimately poorer working memory abilities. These results support the presence of a critical time windows during adolescent prefrontal development and uncover mechanisms by which neuronal-microglial interactions shape circuitry and cognitive behavior.

FOURIER-BASED WAVEFORM ANALYSIS DISSOCIATES HUMAN CORTICAL ALPHA RHYTHMS

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Janet Giehl[1,2,3], Markus Siegel[1,2,3]
[1]University of Tuebingen, Dept. Neural Dynamics And Meg, Hertie Institute For Clinical Brain Research, Tuebingen, Germany, [2]University of Tübingen, Centre For Integrative Neuroscience, Tuebingen, Germany, [3]University of Tübingen, Meg Center, Tübingen, Germany

Human cortical alpha oscillations are non-sinusoidal, and the wave shape of neuronal oscillations is an emerging indicator for neurological and neuropsychiatric disease. However, wave-shape analysis has been largely limited to particularly dominant rhythms and has been unable to cover the full space of possible waveform features. Here, we contribute a novel frequency-domain based waveform-analysis method that allows for a parsimonious and comprehensive analysis of non-sinusoidal wave shapes. We applied this novel approach to human cortical alpha oscillations recorded during resting-state using magnetoencephalography (MEG). Our approach allowed us to dissociate up to six different alpha-frequency waveforms, highlighting the potential of our wave-shape analysis approach for the dissociation of neural rhythms in clinical and basic neuroscience.

CHARACTERIZATION OF SLOW OSCILLATIONS AND SPINDLES DURING SLEEP FROM THE JUVENILE TO THE PERI-ADOLESCENT DEVELOPMENTAL STAGE IN RATS

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Julia Fechner[1], María Contreras[1], Candela Zorzo Vallina[2], Jan Born[1], Marion Inostroza[1]
[1]University of Tuebingen, Institute For Medical Psychology Und Behavioral Neurobiology, Tuebingen, Germany, [2]University of Oviedo, Psychology, Oviedo, Spain

Sleep is known to be an important mediator of memory consolidation through the precise temporal coordination of cortical slow oscillations (SOs) and thalamic spindles during slow-wave sleep. These oscillatory hallmarks have been well investigated in adulthood, however, a description of their temporal coordination across early development is missing. We therefore recorded the electroencephalogram (EEG) from skull electrodes over the frontal and parietal cortex in juvenile and peri-adolescent rats at postnatal day (PD)25 and PD31 roughly corresponding to human early childhood and late childhood. We found an increase in the amplitude of frontal and parietal SOs from PD25 to PD31. Additionally, we identified an increase in the number and density of frontal spindles from PD25 to PD31, while no such increase was observed for parietal spindles. Spindle power increased in both frontal and parietal regions in parallel with the increase observed in SO amplitude. As the temporal synchrony between SOs and spindles, we found a similar percentage of spindles coupled to a SOs at both ages, in frontal and parietal recordings. However, phase-locking spindles to the upstate of an SO showed a different topographical trajectory: at frontal recording sites consistent SO-spindle phase-locking was still absent at PD25 and emerged only at PD31 whereas at parietal recording sites, SO-spindle phase-locking was present already at PD25 without further changes at PD31. These results shed light on a gradual emergence of the SO-spindle coupling during development with different trajectories in frontal and posterior cortex regions.

SPECTRAL FINGERPRINTS OF CORTICAL NEUROMODULATION

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Angela Radetz[1,2,3,4], Markus Siegel[1,2,3]
[1]University of Tübingen, Dept. Neural Dynamics And Meg, Hertie Institute For Clinical Brain Research, Tübingen, Germany, [2]University of Tübingen, Centre For Integrative Neuroscience, Tübingen, Germany, [3]University of Tübingen, Meg Center, Tübingen, Germany, [4]University Medical Center of the Johannes Gutenberg-University Mainz, Neuroimaging Center, Mainz, Germany

Pupil size has been established as a versatile marker of noradrenergic and cholinergic neuromodulation, which has profound effects on neuronal processing, cognition, and behavior. However, little is known about the cortical control and effects of pupil-linked neuromodulation. Here, we show that pupil dynamics are tightly coupled to temporally, spectrally, and spatially specific modulations of local and large-scale cortical population activity in the human brain. We quantified the dynamics of band-limited cortical population activity in resting human subjects using magnetoencephalography and investigated how neural dynamics were linked to simultaneously recorded pupil dynamics. Our results show that pupil-linked neuromodulation does not merely affect cortical population activity in a stereotypical fashion. Instead, we identified three frontal, precentral, and occipitoparietal networks, in which local population activity with distinct spectral profiles in the theta, beta, and alpha bands temporally preceded and followed changes in pupil size. Furthermore, we found that amplitude coupling at ~16 Hz in a large-scale frontoparietal network predicted pupil dynamics. Our results unravel network-specific spectral fingerprints of cortical neuromodulation in the human brain that likely reflect both the causes and effects of neuromodulation.

EFFECT OF CLEAR AND DEGRADED NATURAL SPEECH STIMULATION ON PUPIL RESPONSE FROM EYE-TRACKING DATA: A PILOT STUDY

POSTER SESSION 06 - SECTION: OSCILLATIONS AND NEURAL DYNAMICS

Mübeccel Gizem Erkol[1], Arkan Al-Zubaidi[2], Jochem Rieger[2]
[1]Carl Von Ossietzky University Oldenburg, Neurocognitive Psychology, Oldenburg, Germany, [2]University of Oldenburg, Applied Neurocognitive Psychology Lab, Oldenburg, Germany

Several studies showed that an increasing the degradation level of speech will lead to an increase in the pupil dilation response (Zekveld, 2018). However, those studies were designed to test the hypothesis with audio-visual stimuli. This study aimed to evaluate the influence of degraded speech on the pupil dilation response during only listening. In the experiment, participants just listened to the soundtrack of the movie “Forrest Gump” for 2 hours, and eye movements were recorded during the three different conditions: Clear Stimuli (CS), Degraded Stimuli (S2), and Highly Degraded Stimuli (N4). No visual stimuli were presented during the experiment. Participants were told explicitly to focus on the fixation cross on the screen. We hypothesized that an increased response in pupil dilation response is observed when the degradation level of sound increases as well. Due to the small sample size, we conducted micro statistical analysis by applying Kruskal-Wallis Test for each subject separately. Despite the results did not provide a comprehensive conclusion, they might imply that pupil dilation response does not increase in the event of degraded sound during the absence of visual stimuli. Hereupon one possible speculation might be that pupil dilation response is not caused by degraded sound directly. The reason for increased pupil dilation is that when one sensory system is not able to provide information, the other sensory system increases its effort and/or performance to derive information only if the corresponding stimulus is present.

Targeted closed-loop auditory stimulation during sleep has proven to be an efficient way to enhance endogenous brain activities. Recently, different studies have shown that this stimulation technique can also improve memory recalling processes, making it a promise tool for boosting cognitive functions during sleep. Nevertheless, classical experimental setups require the connection, by a trained staff, of scalp EEG electrodes which could be poorly tolerated by subjects. For this reason, in this work we evaluated the possibility to implement an auditory stimulation system based on in-ear EEG sensors. First, we designed especial in-ear electrodes connected in a bipolar configuration. Then, we implemented a previously validated algorithm [1] for the online detection of positive peaks from the in-ear-recorded slow oscillations (SO) of NREM sleep. Upon the detection of a valid peak, we delivered two sound clicks through especial headband speakers. We connected standard C4 and F4 scalp EEG contacts for comparison purposes. We validated the system through naps of 11 healthy subjects. We report that a precise targeted SO phase detection was possible on the in-ear channel, obtaining a preferred stimulation phase in the 70.62% of the cases for the first stimulus. In addition, we observed a strong SO amplitude and spindle power (11-16 Hz) enhancement in the scalp channels after in-ear stimulation compared with a sham condition where the actual sound was not delivered ($p < 0.05$). We believe that the presented in-ear setup represents an important technological advancement that could lead new functional and clinical applications in the future.

DEEP LEARNING-BASED SPIKE SORTING ON EDGE DEVICES

POSTER SESSION 06 - SECTION: NEURO-ELECTRONICS & NEURO-ENGINEERING

János Rokai[1,2], István Ulbert[2,3], Gergely Márton[2,3]
[1]Semmelweis University, János Szentágothai Doctoral School Of Neurosciences, Budapest, Hungary, [2]Research Centre for Natural Sciences, Institute Of Cognitive Neuroscience And Psychology, Budapest, Hungary, [3]Pázmány Péter Catholic University, Faculty Of Information Technology And Bionics, Budapest, Hungary

Today's multi-channel silicon-based probes can generate large amounts of data, providing finer resolution and enabling better separation of the spike clusters. To cope with the increased complexity, several algorithms (so-called spike sorting algorithms) were developed to provide a faster and more accurate data analysis tool. The aim of our project was to assess the performance of deep learning methods and their efficiency regarding the evaluation of high complexity extracellular neural data on edge devices like a tensor processing unit (TPU). A supervised deep learning model was trained to identify and classify extracellular signals. The architecture of the model was selected from a list of well-known, optimized architectures used in the field of deep learning computer vision. The training data consisted of samples of 128x128 dimension semi-synthetic data in order to provide the most accurate ground truth to the model during training. After quantization, the model was transferred and tested on a Coral Development Board Mini, containing a Coral Edge TPU. During the initial supervised training of the model, a mean average precision of 63.04 was achieved on the test dataset. The inference speed of the initial model, with single-precision floating-point weights, could reach 3,17 msec/sample on a high-performance PC, while the quantized model on the development board reached an average speed of 90 msec/sample. Considering the promising results, a conclusion can be made, that by further optimizing the model in the future, a highly efficient, real-time method can be developed for spike sorting, enabling an efficient and near-state-of-art performance on edge devices.

COCHLEAR SPIRAL GANGLION-ON-A-CHIP

POSTER SESSION 06 - SECTION: NEURO-ELECTRONICS & NEURO-ENGINEERING

Ilkem Sevgili, Iwan Roberts, Botian Huang, Manohar Bance
University of Cambridge, Clinical Neurosciences, CAMBRIDGE, United Kingdom

AIMS A key limitation of cochlear implant (CI) performance is the electrical interface with spiral ganglion neurons (SGNs). Therefore, we aim to develop a Spiral Ganglion-on-a-Chip,which combines 3D replication of the anatomy and core structures of the cochlea, along with embedded SGNs and multielectrode arrays (MEAs) to record neuronal responses expected in humans in a controlled and measurable in vitro system. **METHODS** The model consists of 3 main elements: 1)Rat SGNs and human induced pluripotent stem cell (hiPSC)-derived SGNs (in separate models) 2)Custom-made MEAs to measure cellular electrical activity and 3)Custom-designed 3D printed microfluidic chips to replicate the structure of the human cochlea. We focused on developing both the cellular and device aspects of the Spiral Ganglion-on-a-Chip.Our microfluidic device design has been iteratively optimised in order to ensure: accurate anatomical and electrical conductivity representation of the scala tympani(where CIs sit in the cochlea) and reproducible 3D printing and subsequent casting of the precise features of the PDMS casted model. **RESULTS** A casted PDMS device demonstrated good casting of all required microfeatures.Rat SGNs and glial cells were seeded in initial Cochlea-on-a-Chip prototypes and survived for over a month.SGNs extended neurites through the microchannels.We also developed human auditory neuron-like cells from human induced pluripotent stem cells (hiPSCs).These hiPSC-derived SGNs displayed both a similar morphology to rat SGNs and express a neuronal marker TUJ1. **CONCLUSIONS** Spiral Ganglion-on-a-chip that we have been developing and optimizing will enable us to optimize current and future CI stimulation strategies and chemical and biological therapeutics for hearing loss.

LOW-DISTORTION AND LOW-NOISE CMOS AMPLIFIER FOR HIGH-CHANNEL-COUNT NEUROELECTRONIC INTERFACES

POSTER SESSION 06 - SECTION: NEURO-ELECTRONICS & NEURO-ENGINEERING

Beata Trzpil-Jurgielewicz[1], Władysław Dąbrowski[1], Paweł Jurgielewicz[1], Ewa Kublik[2], Piotr Wiącek[1], Paweł Hottowy[1]
[1]AGH University of Science and Technology, Faculty of Physics and Applied Computer Science, Department Of Particle Interactions And Detection Techniques, Krakow, Poland, [2]Nencki Institute of Experimental Biology, Laboratory Of Emotions Neurobiology, Warsaw, Poland

Aims We present electrical and electrophysiological measurements of a new CMOS neural signals preamplifier. The design addresses the common problem of neural amplifiers with tunable lower cutoff frequency: high nonlinear distortion (>10% of Total Harmonic Distortion) of slow (~ 1 Hz), large-amplitude (a few mV) signals. Methods The main goal of the presented design was to reduce significantly the nonlinear distortion introduced by the standard AC coupling circuit while preserving low noise, low power and small silicon area of the amplifier. Results The measured THD values were below 0.8% for the frequency range 1-10000 Hz and amplitudes up to 10 mV p-p. The noise measured with Neuronexus probe (177 μm^2 iridium sites) was 6.5 µV and 7.2 µV in 1-300 Hz, 300–10000 Hz range respectively. The chip recorded wide-band electrophysiological signals with high-amplitude (up to 5 mV) field potentials i.e. slow sleep waves and responses evoked in rat barrel cortex by whisker stimulation. Spikes (up to about 1 mV) were also clearly visible. Conclusions Our preamplifier enables recording of the full spectrum of electrophysiological signals with minimal distortion, low noise and adjustable lower cutoff frequency (0.1-10 Hz). The design with its small silicon area (0.0046 mm^2) and low power consumption (7 µW) can become the base for future high-channel-count neuroelectronic interfaces. The complete amplifier with a second gain stage and analog/digital converter is currently under development. Funding This work was supported by Polish National Science Centre grant DEC-2013/10/M/NZ4/00268 (PH). B.T.-J, P.J. have been partially supported by the EU Project POWR.03.02.00-00-I004/16.

Analysis and Reduction of Nonlinear Distortion in AC-Coupled CMOS Neural Amplifiers with Tunable Cutoff Frequencies. Integrated CMOS neural amplifiers are key elements of modern large-scale neuroelectronic interfaces. The neural amplifiers are routinely AC-coupled to electrodes to remove the DC voltage. The large resistances required for the AC coupling circuit are usually realized using MOSFETs that are nonlinear. Specifically, designs with tunable cutoff frequency of the input high-pass filter may suffer from excessive nonlinearity, since the gate-source voltages of the transistors forming the pseudoresistors vary following the signal being amplified. Consequently, the nonlinear distortion in such circuits may be high for signal frequencies close to the cutoff frequency of the input filter. Here we propose a simple modification of the architecture of a tunable AC-coupled amplifier, in which the bias voltages of the transistors forming the pseudoresistor are kept constant independently of the signal levels, what results in significantly improved linearity. Based on numerical simulations of the proposed circuit designed in 180 nm technology we analyze the Total Harmonic Distortion levels as a function of signal frequency and amplitude. We also investigate the impact of basic amplifier parameters-gain, cutoff frequency of the AC coupling circuit, and silicon area-on the distortion and noise performance. The post-layout simulations of the complete test ASIC show that the distortion is very significantly reduced at frequencies near the cutoff frequency, when compared to the commonly used circuits. The THD values are below 1.17% for signal frequencies 1 Hz-10 kHz and signal amplitudes up to 10 mV peak-to-peak. The preamplifier area is only 0.0046 mm and the noise is 8.3 µV in the 1 Hz-10 kHz range. To our knowledge this is the first report on a CMOS neural amplifier with systematic characterization of THD across complete range of frequencies and amplitudes of neuronal signals recorded by extracellular electrodes.

ENGINEERING A STRETCHABLE NERVE-ON-CHIP PLATFORM TO STUDY THE CHANGES IN NERVE CONDUCTION UNDER TENSION IN VITRO

POSTER SESSION 06 - SECTION: NEURO-ELECTRONICS & NEURO-ENGINEERING

Peripheral Neuropathy (PN) is a disease of nerves that can be induced by mechanical stress. Neuropathies are still an irreversible condition as available therapies are limited to symptomatic treatment. Development of restorative treatment requires efficient tools. Current *in vitro* methods mostly rely on random cell cultures lacking the biological complexity necessary to generate translatable results. Thus, nerve-on-a-chip models have recently gained interest as they can emulate better the *in vivo* architecture. However, their development on rigid glass multielectrode arrays (MEA) does not allow to study how mechanical stretch induces neuropathy or can be a regenerative strategy for nerve damage[1]. To address this, we aim to establish a stretchable *in vitro* nerve model platform.The platform consists of a polydimethylsiloxane (PDMS) microstructure[2] with seeding wells connected to 10-8 µm wide directional axon guidance channels that all converge into a mm size nerve-forming output channel. The PDMS microstructure aims to be mounted onto a customized stretchable MEA substrate. When seeding rat DRGs spheroids, we could grow several mm long DRGs axons within our PDMS microstructure on glass. Within 30 days, cells had already formed an axon fascicle in the *in vitro* nerve channel and were viable over 100 days. Moreover, co-cultured Schwann cells elicited myelination around some axonal segments. Overall, our initial feasibility experiments demonstrate the potential of the proposed methodology to facilitate the understanding of the role of tensile stress in neuropathy. *References* Shah et al. A key feature of the brain is organization on multiple scales whether it be nanodomains within the synapse, cortical columns, or the hippocampus. It is likely that such stereotyped organization is required for meaningful neural dynamics. However, experimental limitations make studying the dynamics of neural circuits across several spatiotemporal orders of magnitude *in vivo* difficult in the best of cases. While previous patterned *in vitro* systems provided simple analogs for studying neuronal circuits,[1,2] the connectivity was guided between small groups of ~20-50 neurons while the individual connections between neurons were not influenced. To better approximate the degree of organization *in vivo*, we have developed micro/nanofluidic structures able to guide connectivity from synapses to circuits. By using the difference in diameter of main axonal branches, ~450nm for rat hippocampal neurons, versus dendritic spine diameters, ~100nm, we patterned regions with nanochannels where synapses were able to form between pre and postsynaptic neurons. To validate if spines crossing nanochannels created functional synapses we monitored the calcium flux within the afferent axon and the spine head, neck, and dendrite of the postsynaptic neuron[3]. Though our aim is to use this patterning method to investigate fundamentals of neural computation *in vitro* with a specific focus on Hebbian learning, broader interest may be in using it to investigate the dynamics of individual synapses. Nanowires can be used in a broad range of bio-applications among which are neural implants for brain computer interface or neuroprostheses. We have shown that neurons from the Central Nervous System thrive when cultured on vertical arrays of semi-conductor nanowires (NWs), whereas the growth of glial cells on such arrays is limited compared to when cultured on flat substrates. However, semi-conductor nanowires present challenges in terms of integration in neural implants, such as their integration in a flexible substrate and their resistance to corrosion. We have analyzed the interaction of neuronal cells with NWs made from insulator polymers that are usually used for neural implants. For this purpose, we performed retinal and cortical cell cultures on SU8 and parylene-C polymer NWs. Four µm long SU-8 NWs positively influenced cell adhesion and neurite network formation compared to 1 µm long SU-8 NWs and flat SU-8 substrates. However, flat parylene-C was found to be the best polymer. Although we anticipate that parylene-C NWs might improve cell behavior, it has not yet been possible to obtain parylene-C NWs longer than 2µm. Taken together, these results suggest that arrays of nanowires are promising nanomaterials for designing neural interfaces and that the type of material and shape/dimensions of such nanomaterials play an important role.

IN SEARCH OF NEUROPHYSIOLOGICAL BIOMARKERS OF BINGE DRINKING AND EMOTIONAL EATING AMONG YOUTH

POSTER SESSION 06 - SECTION: NEURO-ELECTRONICS & NEURO-ENGINEERING

Román D. Moreno-Fernández[1], Patricia Sampedro-Piquero[2], Elena Bernabeu[1], Carlos Marchena[1], Raúl Alelú-Paz[1]
[1]Universidad Francisco de Vitoria, Facultad De Educación Y Psicología, Madrid, Spain, [2]Faculty of Psychology. Autonomous University of Madrid., Biological And Health Psychology, Madrid, Spain

Youth is a critical period of development in which heavy alcohol consumption has been related to significant physical, cognitive and emotional alterations. Along with this, it is increasingly common to find adolescents who, besides binge drinking, also present emotional eating, i.e., they eat excessively and unhealthily in the face of stressful events with the aim of reducing their anxiety state. Several studies have found a high degree of comorbidity between eating disorders and alcohol consumption. Despite the relevance of the topic and the consequences that binge eating behaviors have for young people, scarce studies have been focused on this topic and it is necessary to develop more preventive research.
Given that binge eating behaviors usually appear after stressful events in young people, we study in a sample of 18 to 25 year olds whether high levels of anxiety are related to intensive alcohol consumption and emotional eating. For this purpose, we propose an innovative virtual reality methodology that allows us to recreate a homogeneous and controlled stressful situation for all participants. Once exposed to this situation, we analyze whether there are psychological and/or neurophysiological differences between young people who binge eat and those who do not in this type of anxious context. Among these neurophysiological variables, we conduct a study of brain electrical activity by electroencephalogram (EEG). Thus, our main goal is to find possible biomarkers that allow to detect young people at risk of developing possible impulse control disorders, such as substance abuse or eating behavior disorders throughout life.

Building Resilience with Aerobic Exercise: Role of FKBP5.
Both preclinical and clinical studies have pointed that aerobic exercise, at moderate doses, is beneficial at all stages of life by promoting a range of physiological and neuroplastic adaptations that reduce the anxiety response. Previous research about this topic has repeatedly described how the regular practice of aerobic exercise induces a positive regulation of neuroplasticity and neurogenesis-related genes, as well as a better control of the HPA axis function. However, limited progress has been carried out in the integration of neuroendocrine and neuroplastic changes, as well as in introducing new factors to understand how aerobic exercise can promote resilience to future stressful conditions. Resilience is defined as the ability to adapt to stress while maintaining healthy mental and physical performance. Consistent findings point to an important role of FKBP5, the gene expressing FK506-binding protein 51 (FKBP51), as a strong inhibitor of the glucocorticoid receptor (GR), and thus, an important regulator of the stress response. We propose that aerobic exercise could contribute to modulate FKBP5 activity acting as a potential therapeutic approach for mood disorders. In this sense, aerobic exercise is well known for increasing the growth factor BDNF, which by downstream pathways could affect the FKBP5 activity. Therefore, our manuscript has the aim of analyzing how FKBP5 could constitute a promising target of aerobic exercise promoting resilient-related phenotypes.

LPA receptor and chronic stress: Effects on behaviour and the genes involved in the hippocampal excitatory/inhibitory balance.
The LPA receptor, one of the six characterized G protein-coupled receptors (LPA) through which lysophosphatidic acid acts, is likely involved in promoting normal emotional behaviours. Current data suggest that the LPA-LPAreceptor pathway may be involved in mediating the negative consequences of stress on hippocampal function. However, to date, there is no available information regarding the mechanisms whereby the LPA receptor mediates this adaptation. To gain further insight into how the LPA-LPA pathway may prevent the negative consequences of chronic stress, we assessed the effects of the continuous

delivery of LPA on depressive-like behaviours induced by a chronic restraint stress protocol. Because a proper excitatory/inhibitory balance seems to be key for controlling the stress response system, the gene expression of molecular markers of excitatory and inhibitory neurotransmission was also determined. In addition, the hippocampal expression of mineralocorticoid receptor genes and glucocorticoid receptor genes and proteins as well as plasma corticosterone levels were determined. Contrary to our expectations, the continuous delivery of LPA in chronically stressed animals potentiated rather than inhibited some (e.g., anhedonia, reduced latency to the first immobility period), though not all, behavioural effects of stress. Furthermore, this treatment led to an alteration in the genes coding for proteins involved in the excitatory/inhibitory balance in the ventral hippocampus and to changes in corticosterone levels. In conclusion, the results of this study reinforce the assumption that LPA is involved in emotional regulation, mainly through the LPA receptor, and regulates the effects of stress on hippocampal gene expression and hippocampus-dependent behaviour.

Effects of the LPA Receptor Deficiency and Stress on the Hippocampal LPA Species in Mice.
Lysophosphatidic acid (LPA) is an important bioactive lipid species that functions in intracellular signaling through six characterized G protein-coupled receptors (LPA). Among these receptors, LPA is a strong candidate to mediate the central effects of LPA on emotion and may be involved in promoting normal emotional behaviors. Alterations in this receptor may induce vulnerability to stress and predispose an individual to a psychopathological disease. In fact, mice lacking the LPA receptor exhibit emotional dysregulation and cognitive alterations in hippocampus-dependent tasks. Moreover, the loss of this receptor results in a phenotype of low resilience with dysfunctional coping in response to stress and induces anxiety and several behavioral and neurobiological changes that are strongly correlated with mood disorders. In fact, our group proposes that maLPA1-null mice represent an animal model of anxious depression. However, despite the key role of the LPA-LPA-pathway in emotion and stress coping behaviors, the available information describing the mechanisms by which the LPA-LPA-pathway regulates emotion is currently insufficient. Because activation of LPA requires LPA, here, we used a Matrix-Assisted Laser Desorption/ Ionization mass spectrometry-based approach to evaluate the effects of an LPA receptor deficiency on the hippocampal levels of LPA species. Additionally, the impact of stress on the LPA profile was also examined in both wild-type (WT) and the Malaga variant of LPA1-null mice (maLPA-null mice). Mice lacking LPA did not exhibit gross perturbations in the hippocampal LPA species, but the LPA profile was modified, showing an altered relative abundance of 18:0 LPA. Regardless of the genotype, restraint stress produced profound changes in all LPA species examined, revealing that hippocampal LPA species are a key target of stress. Finally, the relationship between the hippocampal levels of LPA species and performance in the elevated plus maze was established. To our knowledge, this study is the first to detect, identify and profile LPA species in the hippocampus of both LPA-receptor null mice and WT mice at baseline and after acute stress, as well as to link these LPA species with anxiety-like behaviors. In conclusion, the hippocampal LPA species are a key target of stress and may be involved in psychopathological conditions.

Effects of genetic deletion versus pharmacological blockade of the LPA receptor on depression-like behaviour and related brain functional activity.
Animal models of psychopathology are particularly useful for studying the neurobiology of depression and characterising the subtypes. Recently, our group was the first to identify a possible relationship between the LPA receptor and a mixed anxiety-depression phenotype. Specifically, maLPA-null mice exhibited a phenotype characterised by depressive and anxious features. However, the constitutive lack of the gene encoding the LPA receptor () can induce compensatory mechanisms that might have resulted in the observed deficits. Therefore, in the present study, we have compared the impact of permanent loss and acute pharmacological inhibition of the LPA receptor on despair-like behaviours and on the functional brain map associated with these behaviours, as well as on the degree of functional connectivity among structures. Although the antagonist (intracerebroventricularly administered Ki16425) mimicked some, but not all, effects of genetic deletion of the LPA receptor on the results of behavioural tests and engaged different brain circuits, both treatments induced depression-like behaviours with an agitation component that was linked to functional changes in key brain regions involved in the stress response and emotional regulation. In addition, both Ki16425 treatment and LPA receptor deletion modified the functional brain maps in a way similar to the changes observed in depressed patients. In summary, the pharmacological and genetic

approaches could ultimately assist in dissecting the function of the LPA receptor in emotional regulation and brain responses, and a combination of those approaches might provide researchers with an opportunity to develop useful drugs that target the LPA receptor as treatments for depression, mainly the anxious subtype.This article has an associated First Person interview with the first author of the paper.

Training memory without aversion: Appetitive hole-board spatial learning increases adult hippocampal neurogenesis.
Learning experiences are potent modulators of adult hippocampal neurogenesis (AHN). However, the vast majority of findings on the learning-induced regulation of AHN derive from aversively-motivated tasks, mainly the water maze paradigm, in which stress is a confounding factor that affects the AHN outcome. Currently, little is known regarding the effect of appetitively-motivated training on AHN. Hence we studied how spatial learning to find food rewards in a hole-board maze modulates AHN (cell proliferation and immature neurons) and AHN-related hippocampal neuroplasticity markers (BDNF, IGF-II and CREB phosphorylation) in mice. The 'Trained' mice were tested for both spatial reference and working memory and compared to 'Pseudotrained' mice (exposed to different baited holes in each session, thus avoiding the reference memory component of the task) and 'Control' mice (exposed to the maze without rewards). In contrast to Pseudotrained and Control mice, the number of proliferating hippocampal cells were reduced in Trained mice, but they notably increased their population of immature neurons assessed by immunohistochemistry. This evidence shows that hole-board spatial reference learning diminishes cell proliferation in favor of enhancing young neurons' survival. Interestingly, the enhanced AHN in the Trained mice (specifically in the suprapyramidal blade) positively correlated with their reference memory performance, but not with their working memory. Furthermore, the Trained animals increased the hippocampal protein expression of all the neuroplasticity markers analyzed by western blot. Results show that the appetitively-motivated hole-board task is a useful paradigm to potentiate and/or investigate AHN and hippocampal plasticity minimizing aversive variables such as fear or stress.

Lysophosphatidic acid-induced increase in adult hippocampal neurogenesis facilitates the forgetting of cocaine-contextual memory.
Erasing memories of cocaine-stimuli associations might have important clinical implications for addiction therapy. Stimulating hippocampal plasticity by enhancing adult hippocampal neurogenesis (AHN) is a promising strategy because the addition of new neurons may not only facilitate new learning but also modify previous connections and weaken retrograde memories. To investigate whether increasing AHN prompted the forgetting of previous contextual cocaine associations, mice trained in a cocaine-induced conditioned place preference (CPP) paradigm were administered chronic intracerebroventricular infusions of lysophosphatidic acid (LPA, an endogenous lysophospholipid with pro-neurogenic actions), ki16425 (an LPA receptor antagonist) or a vehicle solution, and they were tested 23 days later for CPP retention and extinction. The results of immunohistochemical experiments showed that the LPA-treated mice exhibited reduced long-term CPP retention and an approximately twofold increase in the number of adult-born hippocampal cells that differentiated into mature neurons. Importantly, mediation analyses confirmed a causal role of AHN in reducing CPP maintenance. In contrast, the ki16425-treated mice displayed aberrant responses, with initially decreased CPP retention that progressively increased across the extinction sessions, leading to no effect on AHN. The pharmacological treatments did not affect locomotion or general exploratory or anxiety-like responses. In a second experiment, normal and LPA -receptor-deficient mice were acutely infused with LPA, which revealed that LPA -mediated signaling was required for LPA-induced proliferative actions. These results suggest that the LPA/LPA pathway acts as a potent in vivo modulator of AHN and highlight the potential usefulness of pro-AHN strategies to treat aberrant cognition in those addicted to cocaine.

Stress, Depression, Resilience and Ageing: A Role for the LPA-LPA1 Pathway.
Chronic stress affects health and the quality of life, with its effects being particularly relevant in ageing due to the psychobiological characteristics of this population. However, while some people develop psychiatric disorders, especially depression, others seem very capable of dealing with adversity. There is no doubt that along with the identification of

neurobiological mechanisms involved in developing depression, discovering which factors are involved in positive adaptation under circumstances of extreme difficulty will be crucial for promoting resilience.

maLPA1-null mice as an endophenotype of anxious depression.

Anxious depression is a prevalent disease with devastating consequences and a poor prognosis. Nevertheless, the neurobiological mechanisms underlying this mood disorder remain poorly characterized. The LPA1 receptor is one of the six characterized G protein-coupled receptors (LPA1-6) through which lysophosphatidic acid acts as an intracellular signalling molecule. The loss of this receptor induces anxiety and several behavioural and neurobiological changes that have been strongly associated with depression. In this study, we sought to investigate the involvement of the LPA1 receptor in mood. We first examined hedonic and despair-like behaviours in wild-type and maLPA1 receptor null mice. Owing to the behavioural response exhibited by the maLPA1-null mice, the panic-like reaction was assessed. In addition, c-Fos expression was evaluated as a measure of the functional activity, followed by interregional correlation matrices to establish the brain map of functional activation. maLPA1-null mice exhibited anhedonia, agitation and increased stress reactivity, behaviours that are strongly associated with the psychopathological endophenotype of depression with anxiety features. Furthermore, the functional brain maps differed between the genotypes. The maLPA1-null mice showed increased limbic-system activation, similar to that observed in depressive patients. Antidepressant treatment induced behavioural improvements and functional brain normalisation. Finally, based on validity criteria, maLPA1-null mice are proposed as an animal model of anxious depression. Here, for we believe the first time, we have identified a possible relationship between the LPA1 receptor and anxious depression, shedding light on the unknown neurobiological basis of this subtype of depression and providing an opportunity to explore new therapeutic targets for the treatment of mood disorders, especially for the anxious subtype of depression.

FROM DATA TO KNOWLEDGE: AN OPEN, FULLY-AUTOMATED ELECTROENCEPHALOGRAPHY PIPELINE FOR BIOMARKER DISCOVERY

POSTER SESSION 06 - SECTION: NEURO-ELECTRONICS & NEURO-ENGINEERING

Cristina Gil Ávila[1,2], Markus Ploner[1,2,3]
[1]Technical University of Munich, Neurology, School Of Medicine, Munich, Germany, [2]Technical University of Munich, Tum-neuroimaging Center, School Of Medicine, Munich, Germany, [3]Technical University of Munich, Center For Interdisciplinary Pain Medicine,school Of Medicine, Munich, Germany

Aims Biomarker discovery through non-invasive brain imaging techniques such as electroencephalography (EEG) requires reproducible and transparent methods applied to large-scale datasets. We developed a comprehensive and standardized EEG pipeline ranging from data acquisition to analysis and interpretation of findings. It allows an easy and large-scale application of EEG to study changes of brain function in various neuropsychiatric disorders. *Methods* We followed open science practices and the FAIR principles of scientific data management in the design of the pipeline. We designed it specifically –but not exclusively– for mobile EEG devices with dry electrodes. These allow much faster acquisition of data than traditional EEG setups with wet electrodes. Standardized EEG BIDS format was used for reading and storing the data. For preprocessing and analysis, we used elements from two open-source and widely used EEG toolboxes (EEGlab, fieldtrip). Finally, to facilitate interpretation of findings and the application to different neuropsychiatric conditions, we accompany our EEG pipeline with standardized patient reported outcomes that characterize overlapping symptoms across neuropsychiatric disorders (e.g., pain, fatigue, anxiety). *Results* We developed a comprehensive EEG pipeline for fast acquisition, preprocessing and analysis of resting state EEG data. It automatically preprocesses the data and extracts physiologically meaningful EEG features (power, connectivity, network characterization). It facilitates the creation of large-scale datasets and fosters sharing and reusability of the data. It is easy-to-use and applicable to a wide range of neuropsychiatric disorders. *Conclusions* Our pipeline promotes open and reproducible research on brain dysfunction in neuropsychiatric diseases, an indispensable step for robust biomarker discovery.

Longitudinal resting-state electroencephalography in patients with chronic pain undergoing interdisciplinary multimodal pain therapy.
Chronic pain is a major healthcare issue posing a large burden on individuals and society. Converging lines of evidence indicate that chronic pain is associated with substantial changes of brain structure and function. However, it remains unclear which neuronal measures relate to changes of clinical parameters over time and could thus monitor chronic pain and treatment responses. We therefore performed a longitudinal study in which we assessed clinical characteristics and resting-state electroencephalography data of 41 patients with chronic pain before and 6 months after interdisciplinary multimodal pain therapy. We specifically assessed electroencephalography measures that have previously been shown to differ between patients with chronic pain and healthy people. These included the dominant peak frequency; the amplitudes of neuronal oscillations at theta, alpha, beta, and gamma frequencies; as well as graph theory-based measures of brain network organization. The results show that pain intensity, pain-related disability, and depression were significantly improved after interdisciplinary multimodal pain therapy. Bayesian hypothesis testing indicated that these clinical changes were not related to changes of the dominant peak frequency or amplitudes of oscillations at any frequency band. Clinical changes were, however, associated with an increase in global network efficiency at theta frequencies. Thus, changes in chronic pain might be reflected by global network changes in the theta band. These longitudinal insights further the understanding of the brain mechanisms of chronic pain. Beyond, they might help to identify biomarkers for the monitoring of chronic pain.

Temporal-spectral signaling of sensory information and expectations in the cerebral processing of pain.
The perception of pain is shaped by somatosensory information about threat. However, pain is also influenced by an individual's expectations. Such expectations can result in clinically relevant modulations and abnormalities of pain. In the

brain, sensory information, expectations (predictions), and discrepancies thereof (prediction errors) are signaled by an extended network of brain areas which generate evoked potentials and oscillatory responses at different latencies and frequencies. However, a comprehensive picture of how evoked and oscillatory brain responses signal sensory information, predictions, and prediction errors in the processing of pain is lacking so far. Here, we therefore applied brief painful stimuli to 48 healthy human participants and independently modulated sensory information (stimulus intensity) and expectations of pain intensity while measuring brain activity using electroencephalography (EEG). Pain ratings confirmed that pain intensity was shaped by both sensory information and expectations. In contrast, Bayesian analyses revealed that stimulus-induced EEG responses at different latencies (the N1, N2, and P2 components) and frequencies (alpha, beta, and gamma oscillations) were shaped by sensory information but not by expectations. Expectations, however, shaped alpha and beta oscillations before the painful stimuli. These findings indicate that commonly analyzed EEG responses to painful stimuli are more involved in signaling sensory information than in signaling expectations or mismatches of sensory information and expectations. Moreover, they indicate that the effects of expectations on pain are served by brain mechanisms which differ from those conveying effects of sensory information on pain.

Dynamics of brain function in patients with chronic pain assessed by microstate analysis of resting-state electroencephalography.
Chronic pain is a highly prevalent and severely disabling disease that is associated with substantial changes of brain function. Such changes have mostly been observed when analyzing static measures of resting-state brain activity. However, brain activity varies over time, and it is increasingly recognized that the temporal dynamics of brain activity provide behaviorally relevant information in different neuropsychiatric disorders. Here, we therefore investigated whether the temporal dynamics of brain function are altered in chronic pain. To this end, we applied microstate analysis to eyes-open and eyes-closed resting-state electroencephalography data of 101 patients suffering from chronic pain and 88 age- and sex-matched healthy controls. Microstate analysis describes electroencephalography activity as a sequence of a limited number of topographies termed microstates that remain stable for tens of milliseconds. Our results revealed that sequences of 5 microstates, labelled with the letters A to E, consistently described resting-state brain activity in both groups in the eyes-closed condition. Bayesian analysis of the temporal characteristics of microstates revealed that microstate D has a less predominant role in patients than in controls. As microstate D has previously been related to attentional networks and functions, these abnormalities might relate to dysfunctional attentional processes in chronic pain. Subgroup analyses replicated microstate D changes in patients with chronic back pain, while patients with chronic widespread pain did not show microstates alterations. Together, these findings add to the understanding of the pathophysiology of chronic pain and point to changes of brain dynamics specific to certain types of chronic pain.

Modulating Brain Rhythms of Pain Using Transcranial Alternating Current Stimulation (tACS) - A Sham-Controlled Study in Healthy Human Participants.
Chronic pain is a major health care problem. A better mechanistic understanding and new treatment approaches are urgently needed. In the brain, pain has been associated with neural oscillations at alpha and gamma frequencies, which can be targeted using transcranial alternating current stimulation (tACS). Thus, we investigated the potential of tACS to modulate pain and pain-related autonomic activity in an experimental model of chronic pain in 29 healthy participants. In 6 recording sessions, participants completed a tonic heat pain paradigm and simultaneously received tACS over prefrontal or somatosensory cortices at alpha or gamma frequencies or sham tACS. Concurrently, pain ratings and autonomic responses were collected. Using the present setup, tACS did not modulate pain or autonomic responses. Bayesian statistics confirmed a lack of tACS effects in most conditions. The only exception was alpha tACS over somatosensory cortex where evidence was inconclusive. Taken together, we did not find significant tACS effects on tonic experimental pain in healthy humans. Based on our present and previous findings, further studies might apply refined stimulation protocols targeting somatosensory alpha oscillations. TRIAL REGISTRATION: The study protocol was pre-registered at ClinicalTrials.gov (NCT03805854). PERSPECTIVE: Modulating brain oscillations is a promising approach for the treatment of pain. We therefore applied transcranial alternating current stimulation (tACS) to modulate experimental pain in healthy participants. However, tACS did not modulate pain, autonomic responses, or EEG oscillations. These findings help to shape future tACS studies for the treatment of pain.

A NEW REAL-TIME EEG SOURCE LOCALIZATION METHOD

POSTER SESSION 06 - SECTION: NEURO-ELECTRONICS & NEURO-ENGINEERING

Valentin Debenay[1], Grégory Turbelin[2], Amine Chellali[3], Marie-Hélène Ferrer[4], Béatrice Alescio-Lautier[5], Jean-Pierre Issartel[2]
[1]Université d'Evry-Val d'Essonne, Ibisc/lmee, ÉVRY-COURCOURONNES, France, [2]Université d'Evry Val d'Essonne, Lmee, Evry cedex, France, [3]Université d'Evry Val d'Essonne, Ibisc, Evry cedex, France, [4]IRBA, Unité Neurophysiologie Du Stress, Brétigny-sur-Orge, France, [5]CNRS/Aix Marseille Université, Lnc, Marseille, France

Aims: Electroencephalography (EEG) provides insights for monitoring brain activity. Unfortunately, although scalp EEG can provide clinically useful information, its spatial resolution is low, making it difficult to determine the specific brain locations involved. However, noninvasive EEG-based source localization methods computationally estimate the locations, orientations, and strengths of the electric currents in the brain generating scalp potentials. Using anatomically faithful 3D head models, these approaches enable the accurate localization of epileptogenic foci, improve surgical efficacy, contribute to the improvement of critical care monitoring, and provide guidance for patient-tailored treatment. Our goal is to determine whether our method of source localization, called "Renormalization", is helpful for obtaining real-time feedback. Methods: Our approach is based on the lead field theory. Unlike other methods, ours computes the so-called “visibility field” of the recording system through a “3D Renormalisation” process. Then, to determine the spatial location and the strength of sources producing the potential scalp maps, this field is used to calculate a unique solution to the neuroelectric inverse problem. Results: We used the “Renormalisation” method with an “ANT Neuro eego sports” system and an anatomically realistic 3D head model. The visibility field characterizes the regions in which the recording system concentrates its source identification ability. We used it to provide an accurate real-time spatial mapping of electrical brain activity and characterization (localization, strength, orientation) of localized and distributed sources. Conclusions: By its specificities, we expect that our method will contribute to a better understanding of brain functions and improve the care of brain-injured patients.

Aim: The burst-suppression (BS) patterns emerging on the electroencephalogram (EEG) in deep anesthetic coma are reactive to external stimulation. We aimed to investigate whether this BS reactivity is increased in the epileptic brain.
Methods: Acute experiments were carried out in adult Wistar Albino Glaxo Rijswijk (WAG/Rij) rats, a commonly used genetic model of absence epilepsy which presents characteristic episodes of spike-and-wave discharges (SWD) lasting about 6 seconds on the wake EEG. Age-matched Wistar rats served as control. Cortical EEG recordings were carried out during isoflurane anesthesia. The BS patterns were quantified by the suppression ratio (SR), measuring the fraction of time spent in suppression, over 1-minute intervals. Investigations were carried out at a baseline SR of 40% - 80%. Intermittent photic stimulation (IPS) was delivered to one eye at 0.5 Hz in 1-minute epochs. Given the predominantly crossed visual pathways, the SR was assessed ipsilaterally to minimize the confounding effect of the visual evoked potentials. A BS reactivity index (BSRI) was defined as the reduction in SR that occurred during IPS, relative to the baseline SR recorded just prior to IPS.
Results: The IPS under deep anesthesia did not trigger SWDs. The mean BSRI was 0.2 in controls. In WAG/Rij the mean BSRI was increased by 55%. The difference was reduced after ethosuximide and paradoxically increased after carbamazepine at doses that had no effect on controls.
Conclusion: Our data suggest that measures of burst-suppression EEG reactivity could be useful to assess the hyperexcitability of the epileptic brain.

ASSESSMENT OF THE RAT ISCHEMIC BRAIN BY BURST-SUPPRESSION EEG REACTIVITY

POSTER SESSION 06 - SECTION: NEURO-ELECTRONICS & NEURO-ENGINEERING

Andrei Bordeianu[1], Alexandru Paslaru[1], Laurentiu Tofan[1], Mihai Stancu[1,2], Bogdan Pavel[1], Carmen Denise Zahiu[1], Andrei Ilie[3], Călin Alexandru[4], Ana-Maria Zagrean[1], Leon Zagrean[1], Mihai Moldovan[1,5,6]
[1]Carol Davila University of Medicine and Pharmacy, Center For Excellence In Neuroscience, Department Of Functional Sciences, Bucharest, Romania, [2]Ludwig-Maximilians-University of Munich, Biology, Munchen, Germany, [3]University of Newcastle, Neurology, Royal Victoria Infirmary, Newcastle, United Kingdom, [4]University of Newcastle, Neurology, Newcastle, United Kingdom, [5]University of Copenhagen, Neuroscience, Copenhagen, Denmark, [6]Rigshospitalet, Clinical Neurophysiology, Copenhagen, Denmark

Aim: The electroencephalographic (EEG) assessment of the diffuse ischemic brain injury remains methodologically challenging. The aim of this study was to investigate the impairment in EEG reactivity to intermittent photic stimulation (IPS) following experimental global cerebral ischemia. Rather than focusing on continuous EEG measures, we tested the reactivity of the discontinuous burst-suppression (BS) patterns induced in deep anesthetic coma. Methods: Male Wistar rats were surgically exposed to a mild global cerebral ischemia by electrocauterization of the vertebral arteries and the subsequent clamping of both common carotid arteries for 5 minutes under laser doppler control. A group of rats exposed to sham surgery served as controls. Cortical EEG recordings were carried out at 48 hours after surgery when all rats appeared clinically recovered. The BS patterns, induced by an overdose of Chloral hydrate, were quantified by the suppression ratio (SR), measuring the fraction of time spent in suppression, over 1-minute intervals. The IPS was delivered to one eye at 0.5 Hz in 1-minute epochs. The BS reactivity index (BSRI) was defined as the reduction in the ipsilateral SR that occurred during IPS, relative to the baseline SR recorded just prior to IPS. Results: At a baseline SR of 40%-80%, the mean BSRI was 0.27 in controls. In contrast, the mean BSRI was about 3-fold smaller in the rats exposed to GCI. The amplitude of the visual evoked potentials was similar between the groups. Conclusion: Our data suggest that measures of burst-suppression EEG reactivity are sensitive to detect the post-ischemic brain injury.

Vagus nerve stimulation is a modern effective method of neuromodulation. Due to reducing anxiety and burnout auricular VNS improves the cognitive function. The aim of the current study was to evaluate the effects of the non-invasive vagus nerve stimulation (VNS) and sham stimulation (SHAM) on visual emotional information perception. 6 right-handed male volunteers aged 18-22 years (Mage= 18.00) participated in VNS study. 5 right-handed male volunteers aged 18-22 years (Mage= 18.00) participated in SHAM study. We used the combination of pleasant meditative classical music and a slow bi-polar wave (0.1-0.2 Hz) of electrical non-invasive transcutaneous auricular vagus nerve stimulation for 5 minutes. The set of 4 VNS was performed at intervals of 3 days. The participants were presented a set of alarming images, taken from the NAPS database (The Nencki Affective Picture System). After 1th session of VHS event-related EEG activity analysis detected activation of cortical structures involved in the stimulus processing (verbal memory (Fz) and cognitive processes (P3)) 600-800 ms after visual stimuli exposition. 4th VHS session leaded to changes of the temporal pattern of processing visual emotional information: we observed the activation of processes associated with emotional understanding (750 ms after the stimuli presentation), processes associated with attention, judgments formation and verbal memory (1200 ms). We may conclude that vagus nerve stimulation has enhanced the cognitive processes involved in the processing of stimuli and changed the temporal pattern of processing visual emotional information.

PERFORMANCE OF NOVEL EEG-BASED ARTEFACT DETECTION METHODS IN SIMULTANEOUS NEUROPHYSIOLOGICAL AND HEMODYNAMIC RECORDINGS

POSTER SESSION 06 - SECTION: NEURO-ELECTRONICS & NEURO-ENGINEERING

Rachel Nuttall[1], Sebastian Berger[1], Cilia Jäger[2], Afra Wohlschläger[2], Gerhard Schneider[1]
[1]Klinikum Rechts der Isar Technical University of Munich, Anesthesiology And Intensive Care, München, Germany, [2]Klinikum Rechts der Isar Technical University of Munich, Neuroradiology, Munich, Germany

Aims: Simultaneous EEG-fMRI holds promise as a method offering novel insights into spatiotemporal circuit-level mechanisms in humans. Artefacts are induced in the EEG by the MR environment, caused by magnetic field gradient switches and electrode movement from scalp pulsations related to cardiac activity. Canonical methods rely upon unmet assumptions and the presence of additional recordings for artefact detection: gradient switch (GS) onsets and ECG. Without these, artefacts cannot be corrected, and the dataset deemed unusable. We have developed methods that enable the detection of GS/cardioballistic (CB) artefacts in the absence of additional/useable recordings. Objective: Validate the performance of our alternative methods against the canonical standard. **Methods:** 64-channel EEG-fMRI data from 26 healthy subjects during eyes-closed rest was analysed. GS onsets from the MR scanner and ECG were recorded. Sensitivity/specificity values were compared for pre-recorded (canonical) GS onsets versus those estimated in our automated method. Similarly, sensitivity/specificity values were compared for CB onsets as estimated from the ECG (canonical, Christov, 2004) versus our EEG-based semi-automated approach. **Results:** GS onset detection: Pre-recorded onsets yielded 100% sensitivity/100% specificity; Our method yielded 100% sensitivity/100% specificity. CB onset detection: Canonical standard yielded onsets with a mean sensitivity of 98.06% (std=1.74%) and specificity of 99.13% (std=1.77%). Our method yielded a mean sensitivity of 99.14% (std=1.42%) and specificity of 98.82% (std=1.05%). **Conclusions:** Our alternative methods (applicable to single-channel data) allow for artefact estimation from clean EEG data to a similar standard as canonical methods in the absence/useability of additional signals with clear advantages to the canonical approaches.

A DEEP LEARNING APPROACH TO MOTOR UNIT NUMBER ESTIMATION

POSTER SESSION 06 - SECTION: NEURO-ELECTRONICS & NEURO-ENGINEERING

Mihai Moldovan[1,2], Christian Krarup[1,2]
[1]Rigshospitalet, Clinical Neurophysiology, Copenhagen, Denmark, [2]University of Copenhagen, Neuroscience, Copenhagen, Denmark

Transcutaneous stimulation of a peripheral nerve with currents of increasing intensity evokes over the innervated muscle a compound motor action potential (CMAP) of increasing amplitude until all motor units are activated. Motor unit number estimation (MUNE) from such a muscle scan (MScan) remains a challenging problem, as it relies on fitting complex mathematical models. We propose a novel approach to MUNE, by harnessing the advances in deep neuronal networks. MScanFit (Bostock H., Muscle Nerve 2016: 889) introduced a simplified MScan model characterizing each motor unit by 3 parameters: amplitude, threshold and threshold variability. In addition, the model included a baseline noise and a cumulated noise of the of the amplitude variability. By varying all the MScanFit model parameters, we generated about 100000 simulated MScans, in the form of 256 x 256 pixels grayscale density images. This simulated dataset with known number of motor units was used for training a deep convolutional network, using a Visual Geometry Group type architecture terminating with a regression layer, referred to as EXMUNE.
We compared MScanFit MUNE and EXMUNE on real MScan recordings collected by stimulating the median nerve at wrist and recording the CMAP over the abductor pollicis brevis muscle. We found that in healthy volunteers, the MUNE was similar for the 2 methods. Nevertheless, in chronic inflammatory demyelinating polyneuropathy and in amyotrophic lateral sclerosis, the loss in motor units detected by EXMUNE was more concordant with conventional needle electromyography.
Our data suggest that deep learning can improve MUNE from MScan in pathology.

A DYNAMIC CLAMP PROTOCOL TO ARTIFICIALLY MODIFY CELL CAPACITANCE

POSTER SESSION 06 - SECTION: NEURO-ELECTRONICS & NEURO-ENGINEERING

Paul Pfeiffer[1], Federico José Barreda Tomás[2], Jiameng Wu[3], Jan-Hendrik Schleimer[1], Imre Vida[2], Susanne Schreiber[1]
[1]Humboldt-Universität zu Berlin, Institute For Theoretical Biology, Berlin, Germany, [2]Charité Universitätsmedizin Berlin, Institute Of Integrative Neuroanatomy, Berlin, Germany, [3]Einstein Center for Neurosciences, Na, Berlin, Germany

Dynamics of excitable cells and networks depend on the membrane time constant, set by membrane resistance and capacitance. Whereas pharmacological and genetic manipulations of ionic conductances of excitable membranes are routine in electrophysiology, experimental control over capacitance remains a challenge. Here, we present capacitance clamp (CapClamp), an approach that allows to mimic a modified capacitance in biological neurons via an unconventional application of the dynamic clamp technique. We first demonstrate the feasibility to quantitatively modulate capacitance in a mathematical neuron model and then confirm the functionality of capacitance clamp in in vitro experiments in granule cells of rodent dentate gyrus with up to threefold virtual capacitance changes. In addition, we show proof-of-concept applications of the CapClamp to study temporal integration, energy consumption and bifurcations of neuronal dynamics. The feedback scheme underlying the CapClamp is easy to adopt in existing dynamic clamp setups and we provide corresponding code for open source dynamic clamp software (RELACS and RTXI). Clamping capacitance provides a flexible tool to investigate the consequences of actual changes of capacitance such as in neuronal growth. As the CapClamp can alter the membrane time constant via capacitance changes while leaving ionic conductances unaffected, it further lends itself to general investigations of neural dynamics, e.g. improving fitting of conductance-based neuron models. Altogether, the presented CapClamp constitutes a novel technique to decipher mechanisms of neuronal signaling in ways that were so far inaccessible to experimental electrophysiology.

Clusters of cooperative ion channels enable a membrane-potential-based mechanism for short-term memory.
Across biological systems, cooperativity between proteins enables fast actions, supra-linear responses, and long-lasting molecular switches. In the nervous system, however, the function of cooperative interactions between voltage-dependent ionic channels remains largely unknown. Based on mathematical modeling, we here demonstrate that clusters of strongly cooperative ion channels can plausibly form bistable conductances. Consequently, clusters are permanently switched on by neuronal spiking, switched off by strong hyperpolarization, and remain in their state for seconds after stimulation. The resulting short-term memory of the membrane potential allows to generate persistent firing when clusters of cooperative channels are present together with non-cooperative spike-generating conductances. Dynamic clamp experiments in rodent cortical neurons confirm that channel cooperativity can robustly induce graded persistent activity - a single-cell based, multistable mnemonic firing mode experimentally observed in several brain regions. We therefore propose that ion channel cooperativity constitutes an efficient cell-intrinsic implementation for short-term memories at the voltage level.

Spatially structured inhibition defined by polarized parvalbumin interneuron axons promotes head direction tuning.
In cortical microcircuits, it is generally assumed that fast-spiking parvalbumin interneurons mediate dense and nonselective inhibition. Some reports indicate sparse and structured inhibitory connectivity, but the computational relevance and the underlying spatial organization remain unresolved. In the rat superficial presubiculum, we find that inhibition by fast-spiking interneurons is organized in the form of a dominant super-reciprocal microcircuit motif where multiple pyramidal cells recurrently inhibit each other via a single interneuron. Multineuron recordings and subsequent 3D reconstructions and analysis further show that this nonrandom connectivity arises from an asymmetric, polarized morphology of fast-spiking interneuron axons, which individually cover different directions in the same volume. Network simulations assuming topographically organized input demonstrate that such polarized inhibition can improve head direction tuning of pyramidal cells in comparison to a "blanket of inhibition." We propose that structured inhibition based on asymmetrical axons is an overarching spatial connectivity principle for tailored computation across brain regions.

Dopamine is a monoamine neurotransmitter with critical roles in the human brain and body. Abnormal alterations in the levels of dopamine can have severe consequences and underly brain disorders such as Parkinson's Disease (PD), Alzheimer's Disease, and Attention Deficit and Hyperactive Disorder. Detecting physiologically relevant dopamine concentrations with high sensitivity in the brain or brain-derived biological samples could bring new early diagnostic and therapeutic approaches for these disorders. However, conventional methodologies to detect dopamine typically have reduced selectivity or sensitivity or long detection cycles. In this work, we developed a novel miniaturized biosensor for dopamine detection based on graphene field-effect transistor (gFET) arrays functionalized with a selective dopamine-specific DNA aptamer. The integration of micron-sized gFETs in an array format permitted label-free ultrasensitive dopamine detection, yielding stable measurements by high-throughput sample measurement replication. With our novel biosensor we reliably detected ultra-low dopamine concentrations in various media, from physiological ionic-strength buffers, such as undiluted phosphate-buffered saline (PBS) and artificial cerebral spinal fluid (aCSF), to complex biological samples. We report record limits-of-detection (LODs) for dopamine, as low as 1 aM (10^{-18}), and wide sensing ranges up to 100 µM (10^{-8}). Furthermore, we show that the multitransistor arrays can detect minimal changes in dopamine concentrations in small working volume biological CSF and striatal brain homogenate samples from a mouse model of PD. These promising results can pave the way for novel point-of-care devices and academic and pharmaceutical research tools that require stable high-throughput detection of physiologically and clinically relevant dopamine concentrations.

Light-driven modulation of neuronal activity at high Spatio-temporal resolution is becoming of high interest in neuroscience. Existing approaches, such as optogenetics, have shown promising results and, as an alternative, we envision using light-sensitive compounds that act without genetic manipulation. Here we engineered and characterized a novel polyconjugated compound (BV-1) that spontaneously and efficiently partitions into the lipid bilayer of primary hippocampal neurons after loading it in the external medium. Neuronal activity is not affected in the dark, whereas millisecond pulses of cyan light induce a robust and persistent depolarization. Our data, based on molecular dynamics simulation, high-speed atomic force microscopy imaging, electrophysiological recordings, and live imaging experiments on lipid bilayers and primary neuronal cultures, suggest the occurrence of two independent light-driven mechanisms: i) formation of pore-like structures that increase membrane permeability to Na^+ and ii) impairment of voltage-gated Na^+ channels activity by putative inhibition of their inactivation-gate. Within seven days after initial incubation, BV-1 is partially internalized, and light-driven membrane depolarization is consequently reduced but still possible to trigger. These properties open up to diverse applications, such as the possibility to employ this compound to perform patch-clamp experiments in a light-controlled perforated configuration. The main advantage of BV-1 is the possibility of modulating membrane perforation using light as a trigger and with significantly faster kinetics compared to conventional antibiotics used for the perforated-patch electrophysiological technique.

AUTOMATED, TWO-PHOTON-TARGETED, MULTI PATCH-CLAMP ROBOT

POSTER SESSION 06 - SECTION: NEURO-ELECTRONICS & NEURO-ENGINEERING

Gema Vera Gonzalez, Phatsimo Kgwarae, Simon Schultz
Imperial College London, Bioengineering, London, United Kingdom

Whole-cell patch-clamp allows for the study of ion channel biophysics, membrane properties, and synaptic responses in intact brains. Multi-patching promises to elucidate the functional and connectivity properties of neuronal microcircuits, but the high skill and labor required (and low throughput) hinders its widespread dissemination. Automated multi-patching may solve this problem, but current 'blind' autopatchers are impractical for targeting secondary cell types. We have developed an automated two-photon-targeted quad-channel patch-clamping technology platform for ex vivo and in vivo electrophysiology, extending the system of Annecchino et al (Neuron 2017,95:1048-55). The platform comprises a two-photon microscope, four micromanipulators fitted with mechanical stability clamps, custom-developed electronically-controlled pressure regulator, patch-clamp amplifier and DAQs. Control is via a custom-developed LabView program which acquires frames directly from the microscope. In ex vivo mode (brain slices), a 3D-stack of the target cells is acquired, and an algorithm detects their center of mass using CFS (contrast focus score). All pipettes then simultaneously step towards their target cells, leaving them in contact. Then the sealing protocol is activated. For in vivo, a closed-loop algorithm is used, where pipettes approach their targets in a step-by-step mode, while the microscope repeatedly acquires images around the targets. After each trial, pipettes are automatically cleaned and returned to their previous positions, allowing for their reuse. Our targeted quad patch-clamp system allows scalable and reproducible electrophysiology studies to be conducted across a variety of laboratory settings, offering for the first time robotically automated recording of subthreshold signals from multiple genetically and optically targeted cells simultaneously.

HUNTING THE MAGNETIC SIGNATURE OF ACTION POTENTIALS

POSTER SESSION 06 - SECTION: NEURO-ELECTRONICS & NEURO-ENGINEERING

Frederike Klein[1], Patrick Jendritza[1], Chloé Chopin[2], Claude Fermon[2], Myriam Pannetier-Lecoeur[2], Pascal Fries[1]
[1]The Ernst Strüngmann Institute (ESI) for Neuroscience in Cooperation with Max Planck Society, Fries Lab, Frankfurt am Main, Germany, [2]CEA Saclay, Spec, Gif-sur-Yvette Cedex, France

Magnetic signals are reference-free, pass through tissue undisturbed and include directional information. Intracranially recorded, they would be a great addition to electrophysiology, potentially providing intracellular information by means of extracellular recording. We have previously demonstrated that magnetic signatures of visually evoked potentials can be recorded with ~30x30µm sensors based on giant magnetoresistance (GMR). Here, we investigate whether it is also possible to record the magnetic signature of single action potentials (APs) with GMRs. We combined GMR and electrophysiological recordings in anesthetized rats (n=8). We limited the voltage across the sensor to avoid tissue warming. When averaging the magnetic field triggered on the thresholded electric spikes, we identified an artifact induced by common electro-magnetic noise on the two sensor types. This was avoided when using spikes from putative single units, identified by spike sorting. When focusing on spikes from 73 clean single-unit clusters with a high number of events (>7000 spikes) we could not identify any apparent signature in the magnetic signal on the sensor close to the putative single units. However, when looking at data from a second magnetic sensor, at 250µm distance, we found a delayed response in the magnetic signal. We hypothesize that this is not the magnetic signature of the AP, but a network effect following the event. We are still convinced that it will be possible to record magnetic signatures of single APs, but the current GMRs are not sensitive enough since the expected signal is very small.

A NON-INVASIVE TECHNIQUE FOR RECORDING THE ELECTRICAL ACTIVITY OF THE HUMAN SPINAL CORD

POSTER SESSION 06 - SECTION: NEURO-ELECTRONICS & NEURO-ENGINEERING

Giulio Gabrieli[1], Cédric Lenoir[2], Rory Bufacchi[1], André Mouraux[2], Giandomenico Iannetti[1]
[1]Italian Institute of Technology, Neuroscience And Behaviour, Rome, Italy, [2]Université Catholique de Louvain, Institute Of Neuroscience, Brussels, Belgium

Aims: This work aims to develop a non-invasive technique to record the electrical activity of the spinal cord by means of active surface electrodes. **Methods:** 64 active electrodes are placed on the skin of the back in 6 columns parallel to the sagittal midline, covering from the cervical (C2) to the thoracic (T8) spinal segments. Interelectrode distance is ~3 cm across both rows and columns. Healthy volunteers participated in 3 different experiments: (1) a passive, fixed rate transcutaneous electrical stimulation of the median nerve; (2) two discrimination tasks, entailing either (a) passive texture stimulation or (b) active object manipulation; (3) finger tapping of different motor sequences at different levels of complexity. A number of post-processing and artifact correction techniques (referencing, ICA, adaptive filtering, and Canonical Correlation Analysis) were employed.
Results: Preliminary results confirmed the possibility of obtaining artifact-free evoked electrical potentials reflecting the electrical activity of the cord following the different types of tasks employed. Importantly, these results are obtained without aggressive preprocessing and extensive computational resources.
Conclusions: A specific electrode montage combined with the preprocessing and analysis pipeline developed for this project might contribute to the development of a non-invasive technology that allows recording the electrical activity of the spinal cord. Such a technique would have important implications in basic and clinical investigations, as well as in the development of novel BCI applications.

Although dendrites act as carriers of synaptic inputs, the nanoscale dimension of their microdomains precludes establishing direct and stable recordings for a sustained period of time, leaving their voltage dynamics poorly understood. To overcome this challenge of electrophysiological access, we developed quartz nanopipettes. Using these nanopipettes we were able to achieve recordings from neuronal dendrites lasting tens of minutes. Identification and characterisation of behavioural dynamics within the spontaneous activity recorded from primary rat and mice neuronal cultures with these nanopipettes revealed a diversity of voltage oscillation patterns. These complex voltage dynamics are a previously unexplored contribution to dendritic computations and may represent intrinsic activity or possibly reflect neuronal network activity.

AIMS: The advent of optogenetics has generated the need of novel implantable tools able to optically control and electrically monitor neural activity. This poses an important technology challenge: the stimulation and readout volumes should overlap as much as possible, requiring light emitters and recording sites very close one to each other. However, this generates photoelectric artifacts due to direct electrode illumination during the stimulation train. In this work we propose a method to exploit mode division in implantable tapered optical fibers to direct stimulation light away from the recording pad. **METHODS:** Tapered optical fibers were coated with a stack of electric and insulating layers patterned with non-planar microfabrication techniques to realize optical emitting points (hereafter referred to as windows) and extracellular recording pads as close as 10µm. The optical behavior of the device was simulated by using Monte-Carlo simulation methods. The obtained multifunctional probes were tested in vivo in Thy1-ChR2 mice. **RESULTS:** We realized multiple devices with different combinations of window/electrode sizes, that were then characterized in terms of light emission patterns and electrochemical impedance. The devices were fist characterized in vitro to confirm the absence of photoelectric noise at power densities ranging from 2 to 10 mW/mm^2, at both high and low frequencies. This allowed for a good superposition of the stimulated and recorded volumes, enabling artefact-free optogenetics in deep brain regions of the living mouse brain.

AN ELECTROPHYSIOLOGICAL INVESTIGATION OF THE EFFECTS OF DIRECT CURRENT STIMULATION OF THE TRIGEMINAL NERVE ON THE RAT HIPPOCAMPUS

POSTER SESSION 06 - SECTION: NEURO-ELECTRONICS & NEURO-ENGINEERING

Liyi Chen, Boateng Asamoah, Myles Mc Laughlin
KU Leuven, Department Of Neuroscience, Leuven Brain Institute, Leuven, Belgium

Background: Transcranial direct current stimulation (tDCS) is a neuromodulation method where low amplitude direct current is passed through scalp electrodes to create a weak electric field in the brain. tDCS was shown to affect many different functions, including memory. Previously it was assumed that the weak field in the brain could explain all the observed neuromodulatory effects. More recent evidence suggests the DC field in the skin may stimulate cranial nerves, such as the trigeminal nerve. These nerves then indirectly cause the observed neuromodulatory effects. However, this indirect mechanism is not fully understood yet. **Methods:** In 4 male Sprague Dawley rats we applied DC stimulation to the trigeminal nerve (0.25 – 3 mA, 3 minutes) while making single unit electrophysiological recordings from the hippocampus (CA1, CA3 and dentate gyrus) using a 32 channel silicon probes. **Results:** The results showed that trigeminal nerve DC stimulation using amplitudes similar to those of conventional tDCS in humans caused increasing spike rates across multiple locations in the hippocampus. This increase lasted up to an hour. **Conclusions:** We showed that tDCS applied to the trigeminal nerve caused a neuromodulatory effect at the level of the hippocampus. These results support the hypothesis that tDCS may work via an indirect peripheral route. The observed effects on the hippocampus may be driven by trigeminal nerve stimulation causing noradrenergic release. More studies could further help to fully understand this tDCS indirect mechanism.

AN ELECTROPHYSIOLOGICAL INVESTIGATION OF THE EFFECTS OF DIRECT CURRENT STIMULATION OF THE TRIGEMINAL NERVE IN THE RAT BRAINSTEM

POSTER SESSION 06 - SECTION: NEURO-ELECTRONICS & NEURO-ENGINEERING

Alireza Majdi, Boateng Asamoah, Myles Mc Laughlin
KU Leuven, Exp Orl, Department Of Neuroscience, Leuven Brain Institute, Leuven, Belgium

Transcranial direct current stimulation (tDCS) is a popular non-invasive brain stimulation method used to modulate many different behavioral and cognitive functions. When low amplitude DC current is passed through the tDCS electrodes on the scalp it is generally assumed that the weak electric field in the brain causes the observed neuromodulation effects. Interestingly, very recent evidence suggests that the stronger electric field in the scalp may stimulate cranial nerves, such as the trigeminal nerve, which indirectly causes the neuromodulation effect. However, the electrophysiological effects of DC stimulation on the trigeminal nerve have, to the best of our knowledge, never before been studied. In 7 male Sprague Dawley rats, we applied direct current (DC) stimulation to the trigeminal nerve (0.25 – 3 mA, 1 minute) while making single-unit electrophysiological recordings from the trigeminal nuclei in the brainstem (primary sensory nucleus of the trigeminal nerve (NVsnpr), and the mesencephalic nucleus, MeV) using a 32 channel silicon probes. The results for 98 single units showed that trigeminal nerve DC stimulation using amplitudes similar to those of conventional tDCS in humans caused an increase in spiking in the trigeminal nuclei. Spike rates decreased after DC stimulation was stopped. The trigeminal nuclei are a key step in transmitting information from the periphery to the cortex. Results show for the first time that DC stimulation of the trigeminal nerve causes an increase in the trigeminal nuclei activity. These results support the idea that some of the observed tDCS effects could be caused by cranial nerve stimulation.

Aim: We recently proposed that the brain electrical activity is comprised of a sequence of alternating oscillatory states with repeating topographic spectral distributions on scalp electroencephalography (EEG), referred to as oscillatory macrostates. The macrostate showing the largest decrease in probability of occurrence measured in percent (reactivity) during sensory stimulation was labelled as the default EEG macrostate (DEM). The aim of this study was to assess whether awareness influences the DEM reactivity (DER). Methods: We included 11 middle cerebral artery ischemic stroke patients with impaired awareness having a median Glasgow Coma Scale (GCS) of 6//15 and a group of 11 matched healthy controls. EEG recordings were carried out during auditory 1-minute stimulation epochs repeating either the subject's own name (SON) or the name in reverse (rSON) which had no discernable meaning at the same acoustic level. The stimuli were generated using a voice synthesizer. The DEM was identified across 3 SON epochs alternating with 3 rSON epochs at 2-minute intervals. The DER was measured from the 1-minute quiet baseline preceding each stimulation epoch (EP3646784B1). The difference in mean DER between SON and rSON epochs, was measured by the salient EEG reactivity (SER). Results: The DER to rSON was about 27% in both controls and patients. The SER was 12.4 ± 2.7 % (Mean ± SEM) in controls and only1.3 ± 1.9 % in the patients (Mann Whitney $p<0.01$). The patient SER increased with the GCS (Pearson $r=0.71$). Conclusion: Our data suggest that the default EEG macrostate reactivity depends on awareness.

Task-driven electroencephalography (EEG) is typically conducted with high-density wet sensor systems, under controlled laboratory conditions. This reduces the size and breadth of cohorts, and limits the technology's potential as an objective marker of functional neurophysiology for patient care and new therapies development. Recent advances have enabled the creation of wireless, 'dry' EEG systems, and easy-to-use engaging tasks emulating standard laboratory paradigms, that can be operated repeatedly by naïve users at-home without expert supervision. We report data from a 4-week long study (n=30 healthy males, mean age=25.6years). Participants were asked to complete gamified tasks unsupervised at home using a Cumulus Neuroscience 16-sensor headset, with tablet for task presentation. We evaluated adherence to the study protocol; quantified data quality by computing the Standard Measurement Error over repeated sessions; and compared results with a reference wet EEG dataset collected from a similar population (Luck et al., 2021). In total, 684 sessions were collected. Participants successfully completed 96% of sessions and reported a mean usability score of 88.3 on the SUS scale. Characteristic event-related potential (ERP) components – the P300 and error-related negativity – were observed in the Oddball and Flanker tasks, respectively. Aggregation of ERPs across sessions (2-4, depending on the task) resulted in grand average signal quality comparable to that of single-session data collected by experts in a laboratory setting using wet EEG. These results indicate that easy-to-use task-driven EEG is a suitable tool for cognitive neuroscience investigations, and has the potential to provide objective, frequent tracking of biomarkers of functional neurophysiology.

Background: Neuroplasticity is often altered in neurodegenerative and psychiatric disorders, and so has relevance as a marker of disease and response to therapy. In preclinical science measures are obtained invasively. In humans measures are high-burden (eg TMS; lab-based EEG) or difficult to link to intervention (eg BNDF).
Aims: The visual evoked potential (VEP) modulation task is based on a paradigm that induces LTP in animals. We evaluated the feasibility of home-based self administration with an easy-to-use dry EEG platform.
Methods: Twelve adults aged 22-48 (7 male, mean age 35.8 [SD 8.8]) received a tablet and Cumulus Neuroscience headset to home. Instructions were given by email and brief video-call. Participants viewed full field checkerboard reversals while counting centrally presented coloured circles. VEPs before and after 5 minutes of 2Hz potentiation were compared. Participants completed 1 session lasting ~11 minutes.
Results: Peak amplitudes of VEP components C1, P1, N1 and P1-N1 peak-to-peak difference were compared at electrode sites O1, O2 and Pz using Fpz as reference (Oz not included in headset configuration). At electrode site Pz there was a significant mean increase in P1 peak amplitude following potentiation (1.52μV [SD 2.76]; t(11)= 3.17; p= .004 uncorrected). **Conclusions:** A VEP modulation paradigm eliciting LTP-like correlates of cortical plasticity can be successfully self-administered in a low-burden session lasting less than 15 minutes. *Figure 1. Group mean pre- (blue) and post- (red)*

potentiation VEPs (n = 12). Y-axis is amplitude in μV. Shading shows 95% confidence intervals.

Brain-wide functional images of freely moving animals are key to understanding how cognitive behaviors may emerge from dynamic activation across different areas of the underlying neural circuitry. Functional Ultrasound (fUS) imaging has recently been demonstrated to robustly record brain-wide cerebral blood volume (CBV) dynamics as an indirect measure of neural activity over several weeks or months in freely moving rodents. Hardware and software interface to couple unrestrained cognitive experiments and fUS data is essential and can provide reliable use of this technique in a wide variety of behavioral paradigms. Here we propose studying freely moving rats in naturalistic behavior exploring an open arena using fUS. Spatial information is extracted using DeepLabCut library and custom pipeline. fUS imaging technology is optimized using a very light 15MHz piezo composite probe and highly flexible cable driven by an Ultrafast Ultrasound scanner (Iconeus One, Iconeus, France). With minimal preprocessing methods on the fUS data, we show encouraging results correlating changes in the CBV of specific brain regions, such as the dorsal hippocampus, with the speed of the animal during its exploration of the environment. In depth analysis of the signal suggests a sequence of activation within these brain regions during animal locomotion. Functional Ultrasound emerges as an interesting tool for unconstrained deep brain imaging during spatial navigation in
rodents.

Introduction. The hypophysis is an endocrine gland located at the base of the brain, weighs less than 1 g and has an average volume of 8 mm^3, it is divided into 2 lobes: an anterior and a posterior. It is established that the disturbance in the secretion of its hormones would be involved in the genesis of eating disorders (ED). **Aims.** The purpose of this study is to create an ATLAS of the hypophysis in order to allow an automatic segmentation, and thus facilitate its morphological and physiological exploration in ED. **Methods.** The anterior and posterior parts of the pituitary glands of 26 healthy subjects were manually delineated on high-resolution MRI T1 images, and automatic atlas-based segmentation of the hypohysis was tested against manual delineation in 32 patients with anorexia nervosa, and 18 athletes. **Results.** With manual delineation, an average total volume of 730 mm^3, 634 mm^3 for the anterior lobe and 96 mm3 for the posterior division. Using the atlas, we get successivly 622 mm^3, 559,7 mm^3 and 62,57 mm^3. The superposition of the voxels with a dice index of 71,1% for the anterior lobe, 46,6% for the posterior lobe, and 71,7% for the global volume. We further describe a morphological modification of the hypophysis in patients with ED and athletes. **Conclusion.** Automatic segmentation atlas-based of hypophysis can subtitute to a manual delineation. The hypophysis atlas could serve for the extraction of binding potentiels (BP), and provide informations on the pathophysiology of this gland in ED and other pathologies.

Frontotemporal dementia (FTD) is a neurodegenerative syndrome with a broad range of clinical manifestations making its early detection and progression monitoring difficult. It is believed that functional connectivity underlies cognitive function which makes it a potential meaningful biomarker. Functional connectivity studies in FTD have provided findings suggesting changes in resting-state networks. However, many of the analysis methods used are either far from the biological processes or restricted to a priori defined networks. Recent work has revealed the emergence of a brain network hierarchy during neurodevelopment, separating immediate environment processing from transmodal cortices; this is assumed to support higher-order cognition. We included 36 behavioural-FTD patients (bvFTD) and 50 controls. We applied a novel whole-brain analysis, connectome-gradient-mapping, to resting-state fMRI data. This approach extracts gradients representing measures of functional similarity, enabling the extent of segregation between networks to be assessed. bvFTD patients showed disruption in macroscale hierarchy affecting integration and segregation of unimodal and transmodal networks. In bvFTD patients, we observed a significant shift of cognitive/behavioural networks (Limbic and Default-mode), which are less segregated from the primary networks (visual and auditory). We found the Default-mode and Limbic networks seem particularly vulnerable in FTD, loosing their evolutionarily-derived characteristics of segregation. These networks underlie complex phenotypes observed in FTD. Next, we will evaluate whether this model could explain the main symptoms of patients, such as disinhibition (Stroop/Hayling tests), alterations in social cognition (miniSEA) and worse general cognition (MMSE). Overall, this method applied to early and/or presymptomatic stages will be of interest in future therapeutic studies for neurodegeneration.

Oxytocin (OXT) is a key modulator of complex socio-affective behavior. However, the brain-wide networks endogenously modulated by OXT remain undetermined. Here, we combine chemogenetics and fMRI[1] to map the topography and dynamics of brain networks engaged by endogenously-released OXT. To this aim, we crossed mice harboring a double-floxed DREADD activator hM3Dq[2] with OXT-specific *Cre*-recombinase mice[3]. We show that the resulting OXT-hM3Dq mice allow physiologically- and behaviorally-relevant release of OXT. Chemo-fMRI mapping of OXT-evoked release revealed prominent functional activation of parietal cortical areas, hypothalamus and dorsal hippocampus. Subsequent resting-state fMRI upon DREADD-based OXT stimulation revealed robustly increased functional connectivity between limbic components of the social brain, and reduced prefrontal-hippocampal cross-talk. Notably, these effects were accompanied by dynamic changes in connectivity characterized by altered coactivation pattern (CAP)[1] topography and distinctive, state-specific changes in fMRI state occurrence. Our work reveals for the first time the network targeted of endogenously released OXT in the mammalian brain, and suggest that endogenous OXT can rapidly and robustly alter functional cross-talk between key components of the social brain via temporal re-organization of network dynamics. 1. Aims: In recent years, fMRI has been established in awake rodents, but one confound facing researchers is that acute stress caused by head fixation and loud acoustic imaging noise is likely to bias the datasets: stress not only impacts the neurobiological function of the brain, but also increases the likelihood of head motion during imaging. Effective habituation may serve to improve the experimental outcome. **Methods:** We assessed faecal corticosterone metabolite levels in rats during gradual habituation to awake fMRI, by conducting an ELISA on the faecal boli. Each sample was analyzed in triplicate. Moreover, we determined the robustness of our procedure exposing the awake rats to an auditory task. **Results:** Although corticosterone levels became elevated immediately after gradual daily habituation began, prolonged daily habituation that involved incremental exposure to the various scanner conditions (physical restraint, head fixation, noise) resulted in a return of corticosterone levels to pre-handling levels. The auditory task revealed the activation of the expected auditory structures, including the auditory cortex which is a very sensitive region – and therefore challenging to detect. **Conclusions:** Our data show how effective acclimatization to the awake fMRI procedures can be achieved by gradual exposure to the experimental conditions over a period of three weeks of training. In the absence of prolonged habituation, experimental data are likely to be confounded by the influence of stress-related elevations in corticosterone. **Acknowledgments:** This work was supported by the German Research Foundation (Deutsche Forschungsgemeinschaft, DFG) (SFB 874/B3, B5, project number: 122679504; SFB 1280/A01, A04: project number: 316803389).

INVESTIGATING THE EFFECTS OF FLOTATION RESTRICTED ENVIRONMENT STIMULATION THERAPY ON NEURAL NETWORKS IN CHRONIC PAIN PATIENTS VIA FUNCTIONAL MAGNETIC RESONANCE IMAGING

POSTER SESSION 06 - SECTION: FUNCTIONAL IMAGING OF THE BRAIN

Tyler Mcgaughey, Victor Finomore
West Virginia University, Neuroscience-rni, Morgantown, United States of America

Millions of Americans suffer from chronic lower back pain (CLBP). Current clinical approaches focus primarily on analgesia through high-strength opioids or invasive surgical interventions. However, these management strategies fail to consider a holistic perspective such as the biopsychosocial approach, which accounts for the long-term effects of both physical and emotional stress caused by CLBP. These factors have a profound effect on key neural networks like the somatosensory and default mode networks. A promising intervention to reduce stress and has altered key brain networks of interest in healthy participants, is Flotation Restricted Environment Stimulation Therapy (REST). REST flotation tanks are designed to reduce auditory, visual, thermal, and tactile stimulation thus allowing the brain to be at rest in a sensory deprived environment. Numerous studies have shown this to be an effective stress management tool with physiological, subjective, and functional effects. This study was designed to evaluate the effects of flotation REST on the neural networks affected by CLBP. Participants underwent a functional magnetic resonance imaging (fMRI) session before and after engaging in six flotation REST session. These scans were contrasted against control participants in a zero-gravity chair. Significant differences was found in resting state connectivity in the somatosensory and default mode networks across conditions. Also, there were significant differences in the prefrontal cortex across over time in the experimental group but not in the control group. These neural changes coupled with subjective alterations in pain show promise for flotation REST as a potential supplemental treatment for CLBP.

FRACTIONAL AMPLITUDE OF LOW-FREQUENCY FLUCTUATION AND REGIONAL HOMOGENEITY IN DOWN SYNDROME. A RELATION WITH COGNITIVE OUTCOME

POSTER SESSION 06 - SECTION: FUNCTIONAL IMAGING OF THE BRAIN

Cristina Cañete-Massé[1], Maria Carbó-Carreté[2], Shi-Xian Cui[3,4], Chao-Gan Yan[3,4], Maribel Peró-Cebollero[1], Joan Guàrdia-Olmos[1]

Introduction: Although clinical and genetic characteristics in the Down Syndrome (DS) population have been described, few neuroimaging research has deepened in this population. Aims: study the whole brain resting state using fractional amplitude of low-frequency fluctuation (fALFF) and regional homogeneity (ReHo) strategies to find differences in spontaneous brain activity among young people with DS and controls. Moreover, this study aims also to find if differences may be related to the neuropsychological evaluation. Methods: 18 persons with DS (M=28,67, SD=4,18) and 18 controls (M=28,56, SD=4,26) matched by chronological age participated in this study. A resting-state registration was done for all the participants, as well as a neuropsychological evaluation, including KBIT-II and phonological and semantic fluency. Results: Regarding fALLF and ReHo analysis, results show significant differences in these frequencies in the whole brain between both compared groups. In this sense, increased and reduced fALLF in DS can reveal abnormal spontaneous activity in some regions. In the same line as in fALFF, results in ReHo show considerable differences between both groups. Regarding correlation analysis with cognitive outcomes, there is a big significant relationship. Moreover, the regressions predicting the signal extraction also have good results. Conclusions: Results are congruent with structural and functional studies done with the same population. Both data-driven methods have shown high sensitivity to find differences between the two populations, and the relationship with neuropsychological evaluation is clear. To our knowledge, it is the first time to explore regional spontaneous brain activity in a population with DS compared to controls.

Complexity Analysis of the Default Mode Network Using Resting-State fMRI in Down Syndrome: Relationships Highlighted by a Neuropsychological Assessment.
Studies on complexity indicators in the field of functional connectivity derived from resting-state fMRI (rs-fMRI) in Down syndrome (DS) samples and their possible relationship with cognitive functioning variables are rare. We analyze how some complexity indicators estimated in the subareas that constitute the default mode network (DMN) might be predictors of the neuropsychological outcomes evaluating Intelligence Quotient (IQ) and cognitive performance in persons with DS.

Task-Related Brain Connectivity Activation Functional Magnetic Resonance Imaging in Intellectual Disability Population: A Meta-Analytic Study.
Neuroimaging studies of intellectual disability (ID) have been published over the last three decades, but the findings are often inconsistent, and therefore, the neural correlates of ID remain elusive. This article aims to study the different publications in task-functional magnetic resonance imaging (fMRI) and different ID populations to make a qualitative and quantitative analysis on this field. After duplicates were removed, only 10 studies matching our inclusion criteria were incorporated. Moreover, a quality assessment of the included studies was done. Qualitative results of the different articles were analyzed, separated by type of task and type of ID. Seed-based d mapping (SDM) software was used. The right temporal gyrus was more activated in control subjects than in ID. Concretely, the right temporal gyrus is implicated in many cognitive domains as semantic memory processing and language. Moreover, it can be highly influenced by the type of task used in every study. Heterogeneity was not detected. A jackknife sensitivity analysis was also estimated to improve the analysis reliability, and

both results were confirmed. More task-fMRI studies on ID must be published to add larger samples to address the pathophysiological questions more directly. Impact statement In this article, the state-of-the-art in the field of functional magnetic resonance imaging (fMRI) and intellectual disability (ID) is reviewed. Moreover, we perform a meta-analysis of every article's results to summarize the principal outcomes in the field. It is very relevant because it has become the first meta-analytic study to overcome all the principal studies published in fMRI and ID to find the principal neurological substrates while the subjects are performing a task.

Structural equation models to estimate dynamic effective connectivity networks in resting fMRI. A comparison between individuals with Down syndrome and controls.
Emerging evidence suggests that an effective or functional connectivity network does not use a static process over time but incorporates dynamic connectivity that shows changes in neuronal activity patterns. Using structural equation models (SEMs), we estimated a dynamic component of the effective network through the effects (recursive and nonrecursive) between regions of interest (ROIs), taking into account the lag 1 effect. The aim of the paper was to find the best structural equation model (SEM) to represent dynamic effective connectivity in people with Down syndrome (DS) in comparison with healthy controls. Twenty-two people with DS were registered in a functional magnetic resonance imaging (fMRI) resting-state paradigm for a period of six minutes. In addition, 22 controls, matched by age and sex, were analyzed with the same statistical approach. In both groups, we found the best global model, which included 6 ROIs within the default mode network (DMN). Connectivity patterns appeared to be different in both groups, and networks in people with DS showed more complexity and had more significant effects than networks in control participants. However, both groups had synchronous and dynamic effects associated with ROIs 3 and 4 related to the upper parietal areas in both brain hemispheres as axes of association and functional integration. It is evident that the correct classification of these groups, especially in cognitive competence, is a good initial step to propose a biomarker in network complexity studies.

Resting-state default mode network connectivity in young individuals with Down syndrome.
Down syndrome (DS) is a chromosomal disorder that causes intellectual disability. Few studies have been conducted on functional connectivity using resting-state fMRI (functional magnetic resonance imaging) signals or more specifically, on the relevant structure and density of the default mode network (DMN). Although data on this issue have been reported in adult DS individuals (age: >45 years), the DMN properties in young DS individuals have not been studied. The aim of this study was to describe the density and structure of the DMN network from fMRI signals in young DS (age: <36 years).

Eliminate the effect of severity of the Personal Outcomes Scale: Linear regression in persons with intellectual disability.
The Personal Outcomes Scale (POS) is used to assess quality of life (QoL) in people with intellectual disability (ID) but the results are influenced by the severity of the disability. To address this issue, we present the standardization of the Spanish adaptation of the POS. One of the limitations of the Classical Test Theory is the differential effect in some items due to the effect of an external variable. For this reason, we propose the use of multiple linear regressions.

Using fMRI to Assess Brain Activity in People With Down Syndrome: A Systematic Review.
In the last few years, many investigations have focused on brain activity in general and in populations with different pathologies using non-invasive techniques such as electroencefalography (EEG), positron emission tomography (PET), functional magnetic resonance imaging (fMRI) and magnetic resonance imaging (MRI). However, the use of non-invasive techniques to detect brain signals to evaluate the cognitive activity of people with Down syndrome (DS) has not been sufficiently addressed. The objective of this study is to describe the state-of-the-art in fMRI techniques for recording brain signals in people with DS. A systematic review was performed based on PRISMA recommendations; only nine papers on this

topic have been published. Three independent researchers selected all relevant information from each paper. Analyses of information concordance showed a high value of agreement between researchers. Although few relevant works have been published, the use of fMRI in people with DS is becoming an appropriate option to study brain function in this population. Of the nine identified papers, five used task designs, and four used resting-state paradigms. Thus, we emphasize the need to incorporate rigorous cognitive activity procedures in evaluations of the DS population. We suggest several factors (such as head correction movements and paired sample techniques) that must be considered when designing an fMRI study with a task or a resting-state paradigm in a DS population.

Longitudinal Estimation of the Clinically Significant Change in the Treatment of Major Depression Disorder.
Although major depressive disorder is usually treated with antidepressants, only 50-70% of the patients respond to this treatment. This study applied Jacobson and Truax's (1991) methodology (reliable change index, RCI) to a sample of depressive patients being treated with one of two antidepressants to evaluate their functioning and the effect of certain variables such as severity and age. Seventy-three depressive patients medicated with Escitalopram (= 37) or Duloxetine (= 36) were assessed using the Hamilton depression rating scale over a 24-week period. They indicate that the RCI stabilizes in an absolute way starting in week 16, and it is not until week 24 that all of the patients become part of the functional population. We found limited statistical significance with respect to the RCI and the external variables. Our study suggests the need to accompany the traditional statistical methodology with some other clinical estimation systems capable of going beyond a simple subtraction between pre and posttreatment values. Hence, it is concluded that RCI estimations could be stronger and more stable than the classical statistical techniques.

VOXELBOXPLUS - A NOVEL TOOL FOR DYNAMIC NETWORK LOCALIZATION OF BRAIN FUNCTIONAL ACTIVITY IN DEMENTIA USING RESTING STATE-FMRI: IMPLICATIONS ON DETECTION, TREATMENT, AND MANAGEMENT

POSTER SESSION 06 - SECTION: FUNCTIONAL IMAGING OF THE BRAIN

Rimjhim Agrawal[1], Akshay Kumaar M[1], Vatsala Nema[2], Dilip Rajeswari[3], Ruchi Sharma[1], Sahana Hegde[1], Laina Emmanuel[1], Ranganayaki Sathyanarayanan[1]

The etiology of dementia has a multifactorial contribution impacted by clinical, cognitive, and cultural factors. The complexity associated with the disease poses a major challenge in terms of its diagnosis and treatment. The goal is to develop neuroimaging indicators that can better treat dementia by understanding brain activity and network relationships using network localization and intrinsic connectivity. This research proposes a novel method named ‘VoxelBox+’ for dynamic network localization of several functional networks of the brain using a sophisticated functional MRI preprocessing pipeline called the ‘VoxelBox’ and Dynamic Canonical Independent Component Analysis to cluster brain activations and map 9 different networks based on Human Connectome Project’s atlas with adaptive template-matching, thresholding, and post-processing. We used 100 subjects in Healthy Controls and Mild Alzheimer’s disease data from the Oasis-3 brain dataset for the network analysis with VoxelBox+. A two-sample t-test was performed for the group-level analysis to find the networks that highly corresponded to Alzheimer's disease. The proposed study found significant differences in the activation of DMN, CEN, DAN, Sensory Motor, and Salience networks between HC and AD subjects with a localization score of ~90%. VoxelBox+’s robust network localization and analysis can prove to be more beneficial for understanding neuropsychiatric symptoms and cognitive-behaviours in patients with dementia at ease using resting state functional MRI.

USE OF PCASL MRI SEQUENCE TO STUDY BRAIN PERFUSION AND VASCULAR PERMEABILITY AFTER BLOOD BRAIN BARRIER OPENING: LIMITATIONS AND PERSPECTIVES.

POSTER SESSION 06 - SECTION: FUNCTIONAL IMAGING OF THE BRAIN

Objective: Contrast enhancement after Gadolinium injection is the gold-standard method for visualizing the opening of the blood-brain barrier. However, it does not allow the assessment of permeability for a smaller molecule such as water. In this study, we evaluated multi-PLD pCASL as a method to assess the change in permeability. **Methods:** BBBO is performed on one hemisphere (Rats, n=5) by US emission at 0.3MPa following the injection of 200µL of microbubbles (SONOVUE-8µL/mL). Control acquisitions (7T/Bruker) are immediately performed. Then, pCASL acquisitions were performed using a LT of 2sec and different PLDs from 10ms to 1100ms. For BBBO visualization, the injection of 300µL of Gadolinium (DOTAREM-0,5mmol/ml) has been followed by T1map acquisition. **Results:** A decrease in ASL signal was observed in the exposed hemisphere (-45.5%) with a recovery within 60min. The volume with ASL signal change is larger than the volume with post-Gd-DOTA contrast enhancement. **Discussion:** The decrease in ASL signal observed in US-impacted areas has two possible causes: a decrease in perfusion related to vasoconstriction *[1]* or, an increase in membrane permeability *[2]*. Despite the multi-PLD method failed to determine their respective contribution, dynamic and spatial evaluation of the ASL signal suggests that the first hypothesis is the most likely. BBBO is generally intended to facilitate drugs permeation to the parenchyma, thus, it would be important to take into account the decrease in brain perfusion resulting in a reduction of the effective amount of drug that reaches the targeted area. *[1] Parkes LM. ASSESSING NEURAL ACTIVITY OF MUSICIANS WITH MUSIC PERFORMANCE ANXIETY: CREATION AND VALIDATION OF THE FMRI SOCIAL-EVALUATIVE MUSIC PERFORMANCE TASK

POSTER SESSION 06 - SECTION: FUNCTIONAL IMAGING OF THE BRAIN

[1]University of Ottawa, Psychology, Ottawa, Canada, [2]University of Ottawa, Music, Ottawa, Canada, [3]University of Ottawa, Psychology, ottawa, Canada

Aims: Music performance anxiety (MPA) is prevalent amongst musicians and can affect musicians' cognition, physiological arousal, and behaviors. However, few studies have focused on the neurophysiological aspects of MPA. This study aimed to create and validate an fMRI task for assessing neural activity associated with MPA. Methods: Twenty musicians with MPA performed a piece of music, individually, in front of judges and rated their subjective anxiety levels. The performance was recorded and was used to create an anxiety-provoking fMRI task that was administered during an MRI scanning session. During the task, participants viewed blocks of videos of themselves performing, videos of another musician's performance, and videos of judges. Results: When examining neural activity during the participant video and panel judging minus neural activity during the control video and panel judging while covarying anxiety scores, there was increased activity in the postcentral gyrus (bilaterally), the superior frontal gyrus, and the middle frontal gyrus. When examining the same contrast without covarying anxiety scores, there was still increased activity in the postcentral gyrus bilaterally and in the superior frontal gyrus; however, the middle frontal gyrus cluster was no longer significant. Conclusions: A new social-evaluative music performance task was successfully implemented in the MRI environment. Results showed brain activity that indirectly represented MPA in areas related to self-reference. Activation related to anxiety scores included regions of the default mode network (DMN), which has been found in previous studies. However, this task was able to tap into this relationship specifically to assess music performance anxiety.

COST FUNCTION MASKING ARTIFICIALLY INFLATES GROUP LEVEL DIFFERENCES IN PROCESSING OF MAGNETIC RESONANCE IMAGING DATA FOR PATHOLOGICAL PATIENT POPULATIONS.

POSTER SESSION 06 - SECTION: FUNCTIONAL IMAGING OF THE BRAIN

Patrik Bey[1,2], Kiret Dhindsa[1,2], Petra Ritter[1,3,4]
[1]Berlin Institute of Health at Charité Universitätsmedizin Berlin, Brain Simulation Section, Berlin, Germany, [2]Charité Universitätsmedizin Berlin, Department Of Neurology With Experimental Neurology, Berlin, Germany, [3]Bernstein Center for Computational Neuroscience Berlin, Bccn, Berlin, Germany, [4]Charité – Universitätsmedizin Berlin, Department Of Neurology And Experimental Neurology, Berlin, Germany

Aims: Cost function masking (CFM) is routinely used to register magnetic resonance imaging (MRI) volumes across modalities or to common templates (Radwan et al. 2021, Andersen et al. 2010, Brett et al. 2001) in the presence of pathological artifacts, such as lesions and tumors. While the impact of pathological abnormalities on downstream analyses is well documented (Andersen et al. 2010, King et al. 2020), the effects of CFM have not yet been thoroughly investigated. Here we aim to quantify the impact on common downstream processing steps. Specifically, we illustrate that applying CFM to a treatment group exhibiting pathological abnormalities in brain structure but not to the control group(s) can affect volumetrics in a statistically biased way, which can in turn influence end-goal hypothesis tests. **Methods** We registered 33 brain extracted T1w images from the ADNI healthy controls dataset to MNI152 template space with and without CFM, creating an artificial grouping based on the same brain volumes. The registered images were segmented using *FSL_fast* (Zhang et al. 2001), and cortical ribbon and white matter masks were compared between groups using dice coefficients and volume ratios (Taha et al. 2015). **Results** We found a strong impact of CFM on tissue segmentation.

Segmentation	Metric	Mean (FSL / ANTS)	Standard deviation (FSL / ANTS)
Cortical ribbon	Dice coefficient	0.8607 / 0.8895	0.0612 / 0.0188
White matter	Dice coefficient	0.8916 / 0.9106	0.0504 / 0.0144
Cortical ribbon	Volume difference	2.885% / 2.369%	1.463% / 0.966%
White matter	Volume difference	3.047% / 0.908 %	1.488% / 0.551%

Table 1 Agreement metrics for CFM versus no CFM segmentation results. With linear registrations using FSL (left) and ANTS (right) software.

Conclusions These findings suggest that statistical group comparisons can be inflated when CFM is applied asymmetrically. Therefore, methods must be developed to account for the bias induced by CFM and related correction methods, particularly when group differences are small. Crucially, the effect on volume estimates impacts downstream analyses, such as connectomics.

Interest in the development of 5-HT2AR agonists, such as psilocybin, for the treatment of multiple neuropsychiatric disorders, has greatly increased. Indeed, in both humans and rodents, psilocybin has been shown to induce persistent mood improvements and alterations in resting-state functional connectivity (rsFC) patterns. However, it remains unknown whether such effects are dose- and/or 5-HT2AR-dependent. Here we aimed at filling these gaps using three cohorts of 10-week-old male C57BL6/J mice. At the behavioral level, alterations in anxiety- and depression-like behaviors (elevated plus maze, open field, and forced swim tests) were assessed 7-days after pretreatment with the selective 5-HT2AR antagonist MDL100907 (vehicle or 0.5mg/kg; i.p.) and subsequent psilocybin administration (vehicle, 1, 2.5 or 5mg/kg; i.p.). Corresponding rsFC alterations are being assessed by functional ultrasound (fUS) recordings in awake mice, immediately after psilocybin (vehicle, 1, 5 or 10mg/kg; i.p.) administration, as well as 7-days after. Furthermore, the role of 5-HT2AR activation will be assessed in a further cohort, by MDL100907 pretreatment (vehicle or 0.5mg/kg; i.p.) previous to psilocybin injection. Behavioral results evidenced a significant dose-dependent anxiolytic-like, but not antidepressant-like, effect of psilocybin, which was abolished by MDL100907 pretreatment, suggesting that 5-HT2AR activation is necessary for these actions. These findings will hold relevance for further mechanistic pre-clinical study of these compounds, in addition to serving as a first step in dissecting the relationship between psilocybin-induced changes in functional connectivity and behavior. Funding: H2020-WIDESPREAD-05-2017-Twinning (EpiEpinet;No.952455), FCT (PTDC/MED-FAR/4834/2021[AMS], SFRH/BD/147505/2019[MF-F]).

Holistic word processing is correlated with efficiency in visual word recognition.
Holistic processing of visual words (i.e., obligatory encoding of/attending to all letters of a word) could be a marker of expert word recognition. In the present study, we thus examined for the first time whether there is a direct relation between the word-composite effect (i.e., all parts of a visual word are fully processed when observers perform a task on a word part) and fast access to the orthographic lexicon by visual word experts (i.e., fluent adult readers). We adopted an individual differences approach and used the word-frequency effect (i.e., faster recognition of high- than low-frequency words) in an independent lexical decision task as a proxy of fast access to lexical orthographic representations. Fluent readers with larger word-composite effect showed smaller word-frequency effect. This correlation was mainly driven by an association between a larger composite effect and faster lexical decision on low-frequency words, probably because these lexical representations are less stable and integrated/unitized, hence allowing differentiating among fluent readers. We thus showed that holistic processing of visual words is indeed related to higher efficiency in visual word recognition by skilled readers.

Hemispheric asymmetry in holistic processing of words.
Holistic processing has been regarded as a hallmark of face perception, indicating the automatic and obligatory tendency of the visual system to process all face parts as a perceptual unit rather than in isolation. Studies involving lateralized stimulus presentation suggest that the right hemisphere dominates holistic face processing. Holistic processing can also be shown with other categories such as words and thus it is not specific to faces or face-like expertize. Here, we used divided visual field presentation to investigate the possibly different contributions of the two hemispheres for holistic word processing. Observers performed same/different judgment on the cued parts of two sequentially presented words in the complete

composite paradigm. Our data indicate a right hemisphere specialization for holistic word processing. Thus, these markers of expert object recognition are domain general.

Anxiety Assessment in Pre-clinical Tests and in Clinical Trials: A Critical Review.
The identification of anxious symptoms is crucial to diagnose anxiety disorders, as well as to monitor their treatment in clinical practice and research. The aim of this review is to discuss the different ways of assessing anxiety in clinical research, including clinical trials, and the different kinds of animal behavioral tests used to study anxiety and test the efficacy of anxiolytics in pre-clinical studies. In clinical practice, a categorical classification (such as the Diagnostic and Statistical Manual of Mental Disorders and the International Statistical Classification of Diseases and Related Health Problems) distinguishes the cases of the disease versus non-disease. Some structured and semi-structured interviews can be used to arrive at these diagnoses. On the other hand, anxiety can also be assessed using a dimensional approach, through self-report or hetero-evaluation questionnaires. Regarding the assessment of anxiety in animals, several behavioral tests are described and evaluated, namely the Social Interaction Test, Elevated Plus Maze and Open Field Test. Under a critical view, these two approaches are presented and discussed, in order to improve the outcome of research in this field.

30430942: Ferreira MF, Castanheira L, Sebastião AM, Telles-Correia D
Depression Assessment in Clinical Trials and Pre-clinical Tests: A Critical Review.
Depression is deeply rooted in human behavior. The development of new antidepressants demands the creation of animal models to investigate new drugs, which potentially could work as antidepressants. The aim of this review is to discuss the different ways of assessing depression in clinical research, including clinical trials, and the different animal behavioral tests used to study depression and test the efficacy of antidepressants in pre-clinical studies. In clinical practice, a categorical classification, such as the Diagnostic and Statistical Manual of Mental Disorders (DSM) and the International Statistical Classification of Diseases and Related Health Problems (ICD) can be used for diagnosis, through the use of structured and semi-structured interviews. On the other hand, depression can also be assessed using a dimensional approach, through self- or clinicianrated questionnaires. Regarding the assessment of the efficacy of antidepressants in animal models, several tests are routinely used, namely the Forced Swim Test, the Modified Forced Swim Test, the Tail Suspension Test and the Sucrose Preference Test. These tests are informative, providing that the following rules are taken into account: 1) more than one test is used, with coherent results; 2) secondary drug effects, the most frequent being putative changes in motor activity, are taken into account and properly controlled with specific tests run concomitantly; 3) each test and specific protocol is validated with data from at least a gold standard antidepressant drug. We herein briefly discuss the potential and limitations of each of those tests.

Hippocampal synaptic dysfunction in the SOD1 mouse model of Amyotrophic Lateral Sclerosis: Reversal by adenosine AR blockade.
Amyotrophic Lateral Sclerosis (ALS) mostly affects motor neurons, but non-motor neural and cognitive alterations have been reported in ALS mouse models and patients. Here, we evaluated if time-dependent biphasic changes in synaptic transmission and plasticity occur in hippocampal synapses of ALS SOD1 mice. Recordings were performed in hippocampal slices of SOD1 and age-matched WT mice, in the pre-symptomatic and symptomatic stages. We found an enhancement of pre-synaptic function and increased adenosine A receptor levels in the hippocampus of pre-symptomatic mice. In contrast, in symptomatic mice, there was an impairment of long-term potentiation (LTP) and a decrease in NMDA receptor-mediated synaptic currents, with AR levels also being increased. Chronic treatment with the AR antagonist KW-6002, rescued LTP and AR values. Altogether, these findings suggest an increase in synaptic function during the pre-symptomatic stage, followed by a decrease in synaptic plasticity in the symptomatic stage, which involves over-activation of AR from early disease stages.

Cannabinoid Actions on Neural Stem Cells: Implications for Pathophysiology.
With the increase of life expectancy, neurodegenerative disorders are becoming not only a health but also a social burden worldwide. However, due to the multitude of pathophysiological disease states, current treatments fail to meet the desired outcomes. Therefore, there is a need for new therapeutic strategies focusing on more integrated, personalized and effective approaches. The prospect of using neural stem cells (NSC) as regenerative therapies is very promising, however several issues still need to be addressed. In particular, the potential actions of pharmacological agents used to modulate NSC activity are highly relevant. With the ongoing discussion of cannabinoid usage for medical purposes and reports drawing attention to

the effects of cannabinoids on NSC regulation, there is an enormous, and yet, uncovered potential for cannabinoids as treatment options for several neurological disorders, specifically when combined with stem cell therapy. In this manuscript, we review in detail how cannabinoids act as potent regulators of NSC biology and their potential to modulate several neurogenic features in the context of pathophysiology.

Of adenosine and the blues: The adenosinergic system in the pathophysiology and treatment of major depressive disorder. Major depressive disorder (MDD) is the foremost cause of global disability, being responsible for enormous personal, societal, and economical costs. Importantly, existing pharmacological treatments for MDD are partially or totally ineffective in a large segment of patients. As such, the search for novel antidepressant drug targets, anchored on a clear understanding of the etiological and pathophysiological mechanisms underpinning MDD, becomes of the utmost importance. The adenosinergic system, a highly conserved neuromodulatory system, appears as a promising novel target, given both its regulatory actions over many MDD-affected systems and processes. With this goal in mind, we herein review the evidence concerning the role of adenosine as a potential player in pathophysiology and treatment of MDD, combining data from both human and animal studies. Altogether, evidence supports the assertions that the adenosinergic system is altered in both MDD patients and animal models, and that drugs targeting this system have considerable potential as putative antidepressants. Furthermore, evidence also suggests that modifications in adenosine signaling may have a key role in the effects of several pharmacological and non-pharmacological antidepressant treatments with demonstrated efficacy, such as electroconvulsive shock, sleep deprivation, and deep brain stimulation. Lastly, it becomes clear from the available literature that there is yet much to study regarding the role of the adenosinergic system in the pathophysiology and treatment of MDD, and we suggest several avenues of research that are likely to prove fruitful.

A CUSTOM CRANIAL WINDOW IMPLANT FOR LONG-TERM WHOLE-BRAIN FUNCTIONAL ULTRASOUND IMAGING IN BEHAVING MICE

POSTER SESSION 06 - SECTION: FUNCTIONAL IMAGING OF THE BRAIN

Bradley Edelman[1,2], Dominique Siegenthaler[2], Emilie Mace[2]
[1]Max Planck Institute of Neurobiology, Circuits For Emotion, Planegg, Germany, [2]Max Planck Institute of Neurobiology, Brain-wide Circuits For Behavior, Planegg, Germany

Behavior emerges from the interplay of multiple circuits across the brain, which emphasizes the importance of observing brain processes at the global scale. Functional ultrasound imaging (fUS) is a unique tool capable of recording rich whole-brain activity in behaving mice. However, high-quality fUS requires direct access to the brain through a cranial window and volumetric imaging requires a large field-of-view, the combination of which makes the associated surgical intervention technically challenging. To simplify and standardize this procedure, we developed a 3D printable resin-based cranial window implant for mice that is compatible with long-term whole-brain imaging during behavioral tasks. We provide a guide for the assembly and installation of the implant as well as a head fixation design compatible with a variety of behavioral setups, including a running wheel and holding tube. We evaluated the robustness and durability of this design by presenting head-fixed mice with a visual stimulation paradigm at over a month after implantation while recording whole-brain activity using fUS. In addition to obtaining brain-wide activation maps in response to visual stimulation, we further demonstrate how the low-profile design of the implant and head fixation facilitates the unobstructed extraction of various behavioral readouts from videographic recordings. This window is acoustically and optically transparent and in practice can be combined with electrode or optic fiber implantations. Therefore, this custom implant can complement a variety of functional neuroimaging modalities, including but not limited to fUS, that benefit from chronic access to a large area of the brain during behavioral mouse experiments.

Noninvasive neuroimaging enhances continuous neural tracking for robotic device control.
Brain-computer interfaces (BCIs) utilizing signals acquired with intracortical implants have achieved successful high-dimensional robotic device control useful for completing daily tasks. However, the substantial amount of medical and surgical expertise required to correctly implant and operate these systems significantly limits their use beyond a few clinical cases. A noninvasive counterpart requiring less intervention that can provide high-quality control would profoundly impact the integration of BCIs into the clinical and home setting. Here, we present and validate a noninvasive framework utilizing electroencephalography (EEG) to achieve the neural control of a robotic device for continuous random target tracking. This framework addresses and improves upon both the "brain" and "computer" components by respectively increasing user engagement through a continuous pursuit task and associated training paradigm, and the spatial resolution of noninvasive neural data through EEG source imaging. In all, our unique framework enhanced BCI learning by nearly 60% for traditional center-out tasks and by over 500% in the more realistic continuous pursuit task. We further demonstrated an additional enhancement in BCI control of almost 10% by using online noninvasive neuroimaging. Finally, this framework was deployed in a physical task, demonstrating a near seamless transition from the control of an unconstrained virtual cursor to the real-time control of a robotic arm. Such combined advances in the quality of neural decoding and the practical utility of noninvasive robotic arm control will have major implications on the eventual development and implementation of neurorobotics by means of noninvasive BCI.

Combined rTMS and virtual reality brain-computer interface training for motor recovery after stroke.
Combining repetitive transcranial magnetic stimulation (rTMS) with brain-computer interface (BCI) training can address motor impairment after stroke by down-regulating exaggerated inhibition from the contralesional hemisphere and encouraging ipsilesional activation. The objective was to evaluate the efficacy of combined rTMS + BCI, compared to sham rTMS + BCI, on motor recovery after stroke in subjects with lasting motor paresis.

EEG Source Imaging Enhances the Decoding of Complex Right-Hand Motor Imagery Tasks.
Sensorimotor-based brain-computer interfaces (BCIs) have achieved successful control of real and virtual devices in up to three dimensions; however, the traditional sensor-based paradigm limits the intuitive use of these systems. Many control signals for state-of-the-art BCIs involve imagining the movement of body parts that have little to do with the output command, revealing a cognitive disconnection between the user's intent and the action of the end effector. Therefore, there is a need to develop techniques that can identify with high spatial resolution the self-modulated neural activity reflective of the actions of a helpful output device.

Repeated hippocampal seizures lead to brain-wide reorganization of circuits and seizure propagation pathways.
Repeated seizure activity can lead to long-term changes in seizure dynamics and behavior. However, resulting changes in brain-wide dynamics remain poorly understood. This is due partly to technical challenges in precise seizure control and in vivo whole-brain mapping of circuit dynamics. Here, we developed an optogenetic kindling model through repeated stimulation of ventral hippocampal CaMKII neurons in adult rats. We then combined fMRI with electrophysiology to track brain-wide circuit dynamics resulting from non-afterdischarge (AD)-generating stimulations and individual convulsive seizures. Kindling induced widespread increases in non-AD-generating stimulation response and ipsilateral functional connectivity and elevated anxiety. Individual seizures in kindled animals showed more significant increases in brain-wide activity and bilateral functional connectivity. Onset time quantification provided evidence for kindled seizure propagation from the ipsilateral to the contralateral hemisphere. Furthermore, a core of slow-migrating hippocampal activity was identified in both non-kindled and kindled seizures, revealing a novel mechanism of seizure sustainment and propagation.

High-sensitivity detection of optogenetically-induced neural activity with functional ultrasound imaging.
Whole-brain imaging approaches and optogenetic manipulations are powerful tools to map brain-wide neural circuits in vivo. To date, functional magnetic resonance imaging (fMRI) provides the most comprehensive evaluation of such large-scale circuitry. However, functional ultrasound imaging (fUSI) has recently emerged as a complementary imaging modality that can extend such measurements towards the context of diverse behavioral states and tasks. Nevertheless, in order to properly interpret the fUSI signal during these complicated scenarios, it must first be carefully validated against well-established technologies, such as fMRI, in highly controlled experimental settings. Here, to address this need, we compared subsequent fMRI and fUSI recordings in response to direct neuronal activation via optogenetics in the same animals under an identical anesthetic protocol. Specifically, we applied various intensities of light stimulation to the primary motor cortex (M1) of mice and compared the spatiotemporal dynamics of the elicited fMRI and fUSI signals. Overall, our general linear model analysis (t-scores) and time series analysis (z-scores) revealed that fUSI was more sensitive than fMRI for detecting optogenetically-induced neuronal activation. Local field potential recordings in the bilateral M1 and striatum also better co-localized with fUSI activation patterns than those of fMRI. Finally, the fUSI response contained distinct arterial and venous components that provide vascular readouts of neuronal activity with vessel-type specificity.

Spatial-temporal aspects of continuous EEG-based neurorobotic control.
The goal of this work is to identify the spatio-temporal facets of state-of-the-art electroencephalography (EEG)-based continuous neurorobotics that need to be addressed, prior to deployment in practical applications at home and in the clinic.Nine healthy human subjects participated in five sessions of one-dimensional (1D) horizontal (LR), 1D vertical (UD) and two-dimensional (2D) neural tracking from EEG. Users controlled a robotic arm and virtual cursor to continuously track a Gaussian random motion target using EEG sensorimotor rhythm modulation via motor imagery (MI) commands. Continuous control quality was analyzed in the temporal and spatial domains separately.Axis-specific errors during 2D tasks were significantly larger than during 1D counterparts. Fatigue rates were larger for control tasks with higher cognitive demand (LR, left- and right-hand MI) compared to those with lower cognitive demand (UD, both hands MI and rest). Additionally robotic arm and virtual cursor control exhibited equal tracking error during all tasks. However, further spatial error analysis of 2D control revealed a significant reduction in tracking quality that was dependent on the visual interference of the physical device. In fact, robotic arm performance was significantly greater than that of virtual cursor control when the users' sightlines were not obstructed.This work emphasizes the need for practical interfaces to be designed around real-world tasks of increased complexity. Here, the dependence of control quality on cognitive task demand emphasizes the need for decoders that facilitate the translation of 1D task mastery to 2D control. When device footprint was accounted for, the introduction of a

physical robotic arm improved control quality, likely due to increased user engagement. In general, this work demonstrates the need to consider both the physical footprint of devices, the complexity of training tasks, and the synergy of control strategies during the development of neurorobotic control.

Exploring Cognitive Flexibility With a Noninvasive BCI Using Simultaneous Steady-State Visual Evoked Potentials and Sensorimotor Rhythms.
EEG-based brain-computer interface (BCI) technology creates non-biological pathways for conveying a user's mental intent solely through noninvasively measured neural signals. While optimizing the performance of a single task has long been the focus of BCI research, in order to translate this technology into everyday life, realistic situations, in which multiple tasks are performed simultaneously, must be investigated. In this paper, we explore the concept of cognitive flexibility, or multitasking, within the BCI framework by utilizing a 2-D cursor control task, using sensorimotor rhythms (SMRs), and a four-target visual attention task, using steady-state visual evoked potentials (SSVEPs), both individually and simultaneously. We found no significant difference between the accuracy of the tasks when executing them alone (SMR-57.9% ± 15.4% and SSVEP-59.0% ± 14.2%) and simultaneously (SMR-54.9% ± 17.2% and SSVEP-57.5% ± 15.4%). These modest decreases in performance were supported by similar, non-significant changes in the electrophysiology of the SSVEP and SMR signals. In this sense, we report that multiple BCI tasks can be performed simultaneously without a significant deterioration in performance; this finding will help drive these systems toward realistic daily use in which a user's cognition will need to be involved in multiple tasks at once.

Systems Neuroengineering: Understanding and Interacting with the Brain.
In this paper, we review the current state-of-the-art techniques used for understanding the inner workings of the brain at a systems level. The neural activity that governs our everyday lives involves an intricate coordination of many processes that can be attributed to a variety of brain regions. On the surface, many of these functions can appear to be controlled by specific anatomical structures; however, in reality, numerous dynamic networks within the brain contribute to its function through an interconnected web of neuronal and synaptic pathways. The brain, in its healthy or pathological state, can therefore be best understood by taking a systems-level approach. While numerous neuroengineering technologies exist, we focus here on three major thrusts in the field of systems neuroengineering: neuroimaging, neural interfacing, and neuromodulation. Neuroimaging enables us to delineate the structural and functional organization of the brain, which is key in understanding how the neural system functions in both normal and disease states. Based on such knowledge, devices can be used either to communicate with the neural system, as in neural interface systems, or to modulate brain activity, as in neuromodulation systems. The consideration of these three fields is key to the development and application of neuro-devices. Feedback-based neuro-devices require the ability to sense neural activity (via a neuroimaging modality) through a neural interface (invasive or noninvasive) and ultimately to select a set of stimulation parameters in order to alter neural function via a neuromodulation modality. Systems neuroengineering refers to the use of engineering tools and technologies to image, decode, and modulate the brain in order to comprehend its functions and to repair its dysfunction. Interactions between these fields will help to shape the future of systems neuroengineering-to develop neurotechniques for enhancing the understanding of whole-brain function and dysfunction, and the management of neurological and mental disorders.

Noninvasive Brain-Computer Interfaces Based on Sensorimotor Rhythms.
Brain-computer interfaces (BCIs) have been explored in the field of neuroengineering to investigate how the brain can use these systems to control external devices. We review the principles and approaches we have taken to develop a sensorimotor rhythm EEG based brain-computer interface (BCI). The methods include developing BCI systems incorporating the control of physical devices to increase user engagement, improving BCI systems by inversely mapping scalp-recorded EEG signals to the cortical source domain, integrating BCI with noninvasive neuromodulation strategies to improve learning, and incorporating mind-body awareness training to enhance BCI learning and performance. The challenges and merits of these strategies are discussed, together with recent findings. Our work indicates that the sensorimotor-rhythm-based noninvasive BCI has the potential to provide communication and control capabilities as an alternative to physiological motor pathways.

Multiple Sclerosis (MS) is a chronically evolving inflammatory disease of the central nervous system caused by focal demyelination. To develop new treatments, new imaging technologies are needed at the preclinical stage to foster therapeutical development. Functional ultrasound imaging (fUSI) has recently been demonstrated to robustly measure brain cerebral blood volume (CBV) dynamics as an indirect measure of neural activity. **Aim:** We postulated that fUSI could allow the definition of biomarkers of demyelinisation / remyelinisation in animal models of MS. The aim of this study was to improve the reproducibility of the experimental conditions and signal processing, in order to use it in preclinical studies involving model systems and pharmacology. **Methods:** We studied the changes of CBV induced by whiskers stimulation in naïve C57Bl6 mice, Cuprizone or Lysolecithin injected mice (N=8 animals/ group), imaged at 5-10 Weeks and 7-14-21 days, respectively. **Results:** First we developed a protocol to trigger the whiskers stimulations and reduce user-dependent variability. The parameters of the stimulation (frequency, duration of stimulation) were optimized, along with the plane of imaging through a fully-automatic ultrasound-based neuro-navigation approach. Finally, this protocol was used in two animal models of MS and showed contrasting results (60% increase CBV in Cuprizone, 50% decrease CBV in Lysolecithin-induced models). **Conclusion**: The measure of evoked hemodynamic response is not a good biomarker of demyelinisation per se, but uncovers interesting mechanisms on demyelination-induced vascular alterations in these models.

The ability to simultaneously record brain activity at multiple temporal and spatial scales is a highly complex quest . In non-human primates (NHP), a combination of fMRI and electrophysiological recordings has been undertaken to elucidate the contributions of spiking activity to the neurovascular response, a question largely debated for several years (Logothetis et al., 2001; Mukamel et al., 2005). Functional ultrasound imaging (fUSi) has recently become a valid but indirect measure to explore brain function in many species, including NHP (Dizeux et al., 2018; Blaize et al., 2020). Even with limited motion artifacts and well-controlled anesthetic states, comparisons between fUSi and extracellular neuronal responses remain an extreme challenge to understand neuronal processing in primates. Here, in reproducible experimental sessions, we present a new set-up achieving simultaneous recordings of cerebral blood flow (CBV) and nearby single-unit activities (SUA) in two behaving macaques' primary visual and fronto-medial cortices. We computed task-induced and SUA-induced CBV activation maps using Generalized Linear Models (GLM) commonly used in fMRI studies. Thereby, using the high spatial resolution of fUSi (~100*100*400 µm^3), our results demonstrate that SUA provides a significant estimate of the neurovascular response. These results have important implications for interpreting functional imaging findings as fMRI or fUSi and physiological inferences guided by explorations of direct neurophysiological activities in awake primates and humans.

NeuroLead is a drug discovery platform, coordinated by Theranexus, Collège de France and CEA, dedicated to neuron-astrocyte communication in physiological and pathological conditions. We present here two complementary *in vivo* approaches to evaluate neuroglial interactions based on calcium signaling and neurovascular coupling. Mice expressing GCaMP6f under the GFAP promoter were lens implanted in the nucleus accumbens to record astroglial calcium fluorescence variations with a head-mountable epifluorescent miniature microscope. Animals were habituated to the system by holding a dummy miniscope for 7 days before to perform a three-chamber test. The imaging system was set up to detect TTL pulses generated by the behavior system to synchronize imaging frames and mouse behavioral activities. We recorded calcium activity of accumbal astrocytes in freely behaving mice performing simultaneously behavioral tests. We found that calcium transients were triggered when mice were interacting in a three-chamber test. In addition to this approach, a functional neuroimaging technique based on neurovascular coupling was designed to locally monitor cerebral blood dynamics in rodents. Functional ultrasound imaging allows, with high spatio-temporal resolution and sensitivity, to record cerebral blood volume dynamics and evaluate functional connectome patterns. Moreover, fUS can be performed in anaesthetized or awake state, during a pharmacological challenge and/or using different stimuli. Through this imaging platform, we present here our ability to monitor both astroglial calcium- and cerebral blood- dynamics using *in vivo* miniscope and functional ultrasound imaging approach respectively. Thus, this *in vivo* platform may constitute a new step to move forward in drug development for neurological disorders.

Aims In contrast to many conventional functional brain imaging modalities, functional Ultrasound (fUS) combines high sensitivity with submillimeter-subsecond spatiotemporal resolution, high-depth penetration and large fields of view. Since its inception over a decade ago there has been no study comparing fUS-acquired functional maps and its gold standard counterpart of BOLD-fMRI imaging. Here we present our first results of combined fUS-fMRI imaging in the same human subject. **Methods** fUS stools on high-sensitivity ultrafast µDoppler ultrasound imaging of microvascular hemodynamics, including changes in cerebral blood flow (CBF) and cerebral blood volume (CBV). Through the principle of neurovascular coupling, these hemodynamics serve as an indirect measure of neuronal activity. In a number of patients undergoing awake craniotomy surgery for tumor removal, we performed paired functional testing with pre-operative fMRI and intra-operative fUS, respectively. Building on clinically available neuro-navigation software, we co-registered both modalities to study spatiotemporal overlap. **Results** In a range of simple motor, visual and language-related functional tasks we were able to confirm fUS-based functional regions using the pre-operative fMRI-map. Our fUS functional maps presented with unprecedented micrometer-millisecond precision, even at depths of over > 5 cm. What is more, fUS was able to concomitantly visualize the in-vivo microvascular morphology underlying these functional hemodynamics. **Conclusions** We present the first in-human confirmation of spatial overlap in functional regions between fUS and fMRI, serving as an important milestone towards further clinical and neuroscientific maturity of fUS as a new cutting-edge functional brain imaging modality.

Wireless closed-loop optogenetics across the entire dorsoventral spinal cord in mice.
Optoelectronic systems can exert precise control over targeted neurons and pathways throughout the brain in untethered animals, but similar technologies for the spinal cord are not well established. In the present study, we describe a system for ultrafast, wireless, closed-loop manipulation of targeted neurons and pathways across the entire dorsoventral spinal cord in untethered mice. We developed a soft stretchable carrier, integrating microscale light-emitting diodes (micro-LEDs), that conforms to the dura mater of the spinal cord. A coating of silicone-phosphor matrix over the micro-LEDs provides mechanical protection and light conversion for compatibility with a large library of opsins. A lightweight, head-mounted, wireless platform powers the micro-LEDs and performs low-latency, on-chip processing of sensed physiological signals to control photostimulation in a closed loop. We use the device to reveal the role of various neuronal subtypes, sensory pathways and supraspinal projections in the control of locomotion in healthy and spinal-cord injured mice.

How to Identify Responders and Nonresponders to Dorsal Root Ganglion-Stimulation Aimed at Eliciting Motor Responses in

Chronic Spinal Cord Injury: Post Hoc Clinical and Neurophysiological Tests in a Case Series of Five Patients.
While integrity of spinal pathways below injury is generally thought to be an important factor in the success-rate of neuromodulation strategies for spinal cord injury (SCI), it is still unclear how the integrity of these pathways conveying the effects of stimulation should be assessed. In one of our institutional case series of five patients receiving dorsal root ganglion (DRG)-stimulation for elicitation of immediate motor response in motor complete SCI, only two out of five patients presented as responders, showing immediate muscle activation upon DRG-stimulation. The current study focuses on post hoc clinical-neurophysiological tests performed within this patient series to illustrate their use for prediction of spinal pathway integrity, and presumably, responder-status.

Functional Ultrasound (fUS) During Awake Brain Surgery: The Clinical Potential of Intra-Operative Functional and Vascular Brain Mapping.
Oncological neurosurgery relies heavily on making continuous, intra-operative tumor-brain delineations based on image-guidance. Limitations of currently available imaging techniques call for the development of real-time image-guided resection tools, which allow for reliable functional and anatomical information in an intra-operative setting. Functional ultrasound (fUS), is a new mobile neuro-imaging tool with unprecedented spatiotemporal resolution, which allows for the detection of small changes in blood dynamics that reflect changes in metabolic activity of activated neurons through neurovascular coupling. We have applied fUS during conventional awake brain surgery to determine its clinical potential for both intra-operative functional and vascular brain mapping, with the ultimate aim of achieving maximum safe tumor resection.

Functional ultrasound (fUS) imaging, a novel and highly sensitive neuroimaging modality with previously unequaled spatiotemporal resolution (1kHz, 100µm), is becoming an increasingly important tool for the study of functional connectivity in awake animals. However, fUS data preprocessing presents significant challenges, in particular considering the confounding effects of artefacts caused by animal motion. While steps which have been previously selected to mitigate these artefacts have often been inspired by fMRI preprocessing pipelines, including global signal regression (GSR), scrubbing and bandpass filtering, their implementation and the order in which they are performed is often controversial and can be critical. Here, we report benchmarking results of the performance of several preprocessing pipelines previously used in functional connectivity studies using fUS imaging, along with new methods inspired by recent advances in fMRI preprocessing. We tested the algorithms on two fUS datasets from longitudinal studies of functional connectivity alterations following pharmacological treatments in mice. This study illustrates the effects that different preprocessing pipelines can have on subsequent statistical analyses and shows that special care must be taken when preprocessing fUS data. The best preprocessing pipeline, selected according to previously established metrics of noise removal, has been implemented in a fUS analysis package, as well as a user-friendly web-application that enables end-to-end analysis of functional ultrasound data acquired in longitudinal pharmacological studies.

[1]Université de Paris, INSERM U1266, Institute Of Psychiatry And Neuroscience Of Paris, Paris, France, [2]Physics for Medicine, Inserm, Espci Paris, Cnrs, Psl Research university, Paris, France, [3]Physics for Medicine, Inserm, Espci Paris, Cnrs, Psl Research University, Paris, France

Functional imaging of hemodynamic signals as a proxy for neuronal activations allowed the emergence of Functional Connectivity (FC) studies non invasively in humans. However, translation back to pre-clinics remains challenging as traditional scanners require almost complete immobility of animals, usually achieved through anaesthesia which interfere with FC. We show here that functional ultrasound brain imaging (fUS) is a good alternative for FC measurement to characterise the pharmacological fingerprints of different drugs in mobile rodents. We describe a standardised platform optimising the different steps of FC measures in awake behaving animals : preparation surgery, habituation to head fixed apparatus, imaging sessions for longitudinal follow up of treatment, data management, fUS oriented analysis pipeline. We compared the effects of opioids and cannabinoids on FC by using specific agonists of the μ-opioid (MOR) and CB1 receptors (CB1R). We report reproducible changes in cortico-cortical, thalamo-cortical and hippocampal connectivity. Additionally, we observe a significant increase in cerebral blood volume (CBV) preceding the shift in FC. Finally, the trigeminal ganglia appears as a main source of signal at baseline with a massive down-regulation mediated by both CB1R and MOR activation. All the observed effects were dose-dependent and reversed after antagonist pre-treatment. The opioid effect was absent in MOR knock-out mice. We conclude that a fast increase of CBV precedes the establishment of a FC fingerprint associated with a change of brain state correlating with known behaviour features. The study of these FC patterns should allow to accelerate screening of drug effects and identify new potential therapies.

NON-INVASIVE TRANSCRANIAL WHOLE BRAIN ANGIOGRAPHY AND HEMODYNAMIC QUANTIFICATION AT THE MICROSCOPIC SCALE IN RODENTS

POSTER SESSION 06 - SECTION: FUNCTIONAL IMAGING OF THE BRAIN

Mathis Vert[1], Mohamed Nouhoum[1], Adrien Bertolo[1], Thomas Deffieux[1], Bruno Osmanski[1], Mickael Tanter[2]
[1]Physics for Medicine, Inserm, Espci Paris, Cnrs, Psl Research university, Paris, France, [2]Physics for Medicine, Inserm, Espci Paris, Cnrs, Psl Research university, Paris, France

In the last decade, Ultrafast ultrasound imaging at thousands of frames per second combined with the intravenous injection of 1-3 µm gas microbubbles led to the concept of Ultrasound Localization Microscopy (ULM). This new modality breaks the fundamental trade-off between spatial resolution and penetration depth of Ultrasound imaging and enables the deep and non-invasive mapping of cerebral vasculature at the microscopic scale both in preclinical and clinical configurations. Additionally, ULM provides quantitative information about hemodynamics (local microbubble speed in the 1-30 mm/s range and microbubble flow). It exhibits several distinct compartments of the vascular tree (arterioles, branching capillaries, venules) and can be spatially linked to the functional and anatomic information through a process of registration to an atlas. For now, ULM has mainly been restricted to single-plane imaging. For 3D imaging, matrix probes still lack sensitivity and impose a great electronic complexity. Here, we introduce a multilinear stacked probe combining four high sensitivity linear ultrasound probes (4x64 elements, 15MHz) to image the whole brain at once. Our protocol is implemented on the Iconeus One ultrasound scanner (256 channels) and consists in translating the probe to four positions to obtain sixteen super-resolution planes in 15 minutes. We achieve a whole-brain quantification of the mouse vascular properties and characterize the spatial heterogeneities of the hemodynamic response under the influence of a vasodilator drug (isoflurane inhalation) in different brain regions.
Whole-brain transcranial angiography at microscopic scale based on ULM imaging gives new insights on the spatial heterogeneities of the vascular system and its associated hemodynamics.

EVALUATION OF THE RELAXIVITY AND CONTRAST ENHANCEMENT OF A NEW MRI MOLECULAR PROBE TARGETING TAU LESIONS IN MOUSE BRAINS : A PILOT STUDY

POSTER SESSION 06 - SECTION: FUNCTIONAL IMAGING OF THE BRAIN

Laura Mouton[1], Mathieu Santin[1], Bay[2], Ganneau[2], Nadege Sarrazin[1], Prigent[1], Lafaye[3], Delatour[1], Petiet[1]
[1]Institut du Cerveau (ICM) - Paris Brain Institute, Inserm U 1127, Cnrs Umr 7225, Sorbonne Université, Paris, France, [2]Institut Pasteur, Unité De Chimie Des Biomolécules, Cnrs Umr 3523, Paris, France, [3]Institut Pasteur, Plateforme D'ingénierie Des Anticorps, C2rt, Umr3528, Paris, France

Aims : Hyperphosphorylated Tau deposits are a hallmark of Alzheimer's disease. Contrary to amyloid plaques, which have endogenous MRI contrast[1], their detection requires targeted molecular MRI contrast agents (CA)[2]. This study evaluates an anti-tau-gadolinium (Gd) CA prototype based on camelid single-domain antibody fragments in P301S transgenic mouse model of tauopathy[3]. **Methods** : CA relaxivity parameters were measured *in vitro* at 11.7T. To bypass the blood-brain barrier, 6 µL of CA (0.5mM [Gd]), Gd (0.45mM [Gd]) or Phosphate Buffer Saline (PBS) were stereotactically injected in 7 month-old P301S mice (right hemisphere). Three to 5h after injection, *in vivo* T1-weighted (T_1w) and T2*-weighted (T_2*w) images were acquired with a Bruker cryoprobe™. Contrast-to-noise ratios (CNR) between ipsilateral and contralateral hemispheres were measured. **Results** : r1 and r2 values were measured to 8.6 and 15.3 $mM^{-1}.s^{-1}$ respectively, with r1 of the same order of magnitude as Dotarem – Gd-based MRI CA reference. A diffuse contrast enhancement was observed on T_1w images in the ipsilateral hemisphere compared to the contralateral one following both CA and Gd injections (Fig1). The CNR enhancement induced by the CA was 30% higher than that induced by Gd alone. No effect was observed following PBS injection. Except for the needle tract, T_2*w images presented no contrast
anomaly.

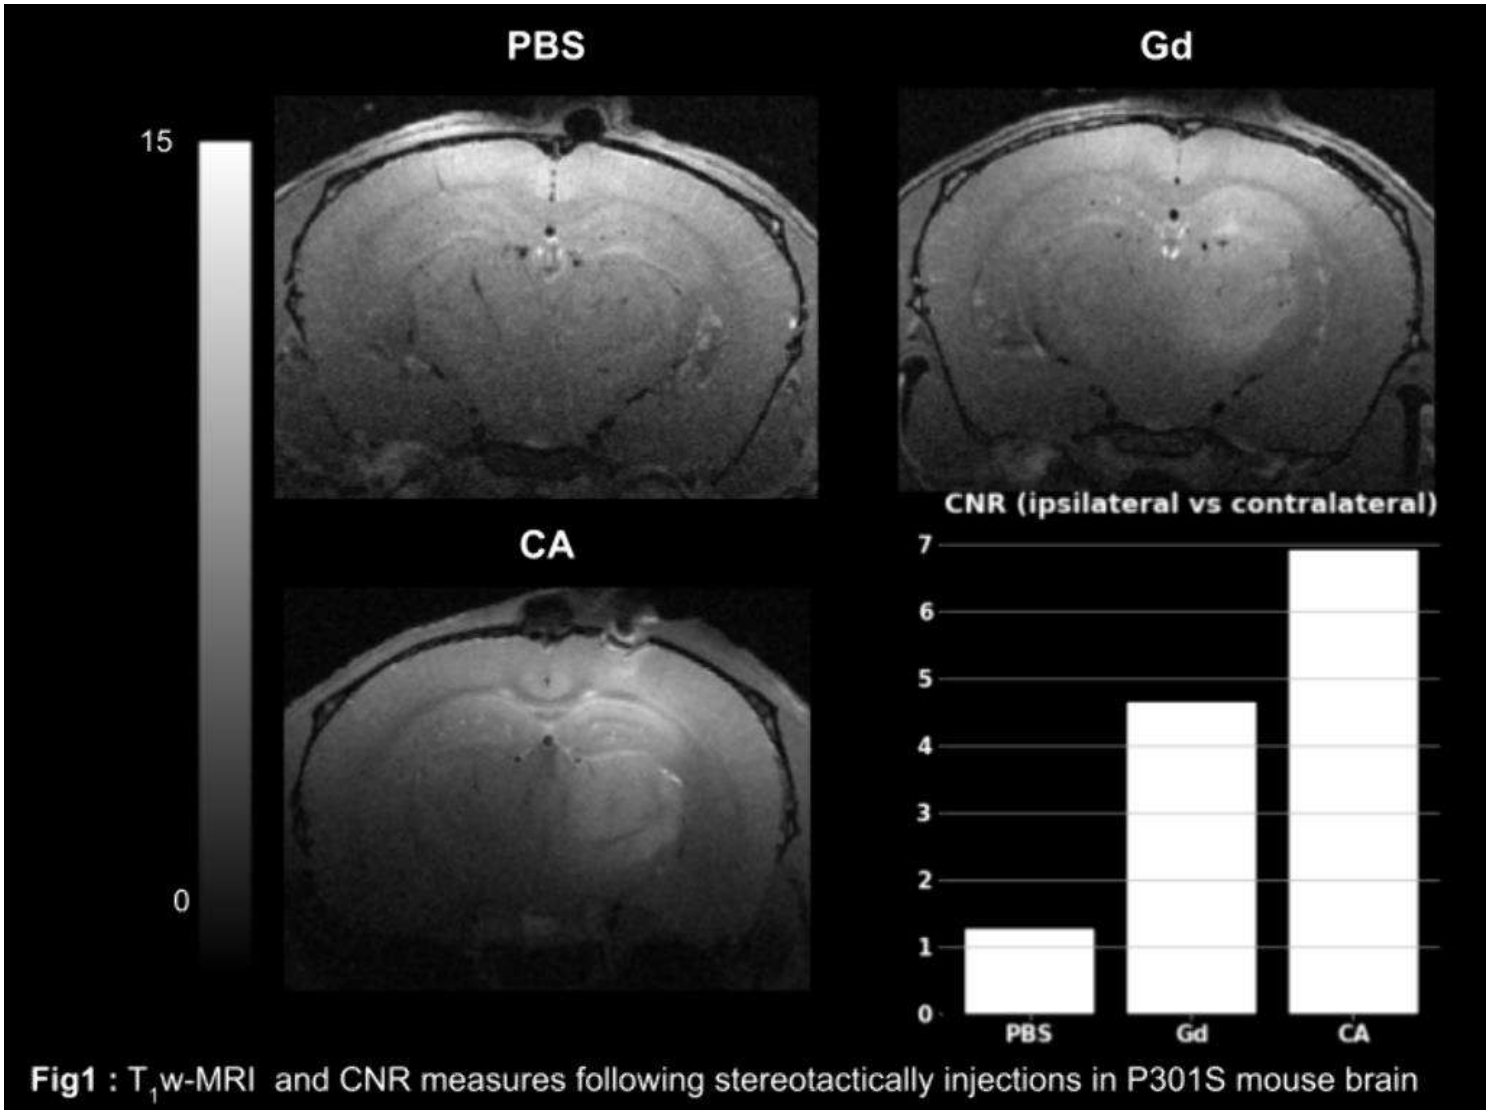

Fig1 : T_1w-MRI and CNR measures following stereotactically injections in P301S mouse brain

Conclusions : The good relaxivity of our CA allowed enhanced contrast compared to Gd alone. Those preliminary results should help detecting Tau deposits and the specificity will be validated with histology. **References :** [1]Petiet, Neurobiol. WHOLE-BRAIN 3D TRANSCRANIAL FUNCTIONAL CONNECTIVITY OF THE MOUSE BRAIN WITH MULTIARRAY FUNCTIONAL ULTRASOUND IMAGING

POSTER SESSION 06 - SECTION: FUNCTIONAL IMAGING OF THE BRAIN

Adrien Bertolo[1,2], Jérémy Ferrier[1], Silvia Cazzanelli[1,2], Mickael Tanter[2], Bruno Osmanski[1], Mathieu Pernot[2], Thomas Deffieux[2]

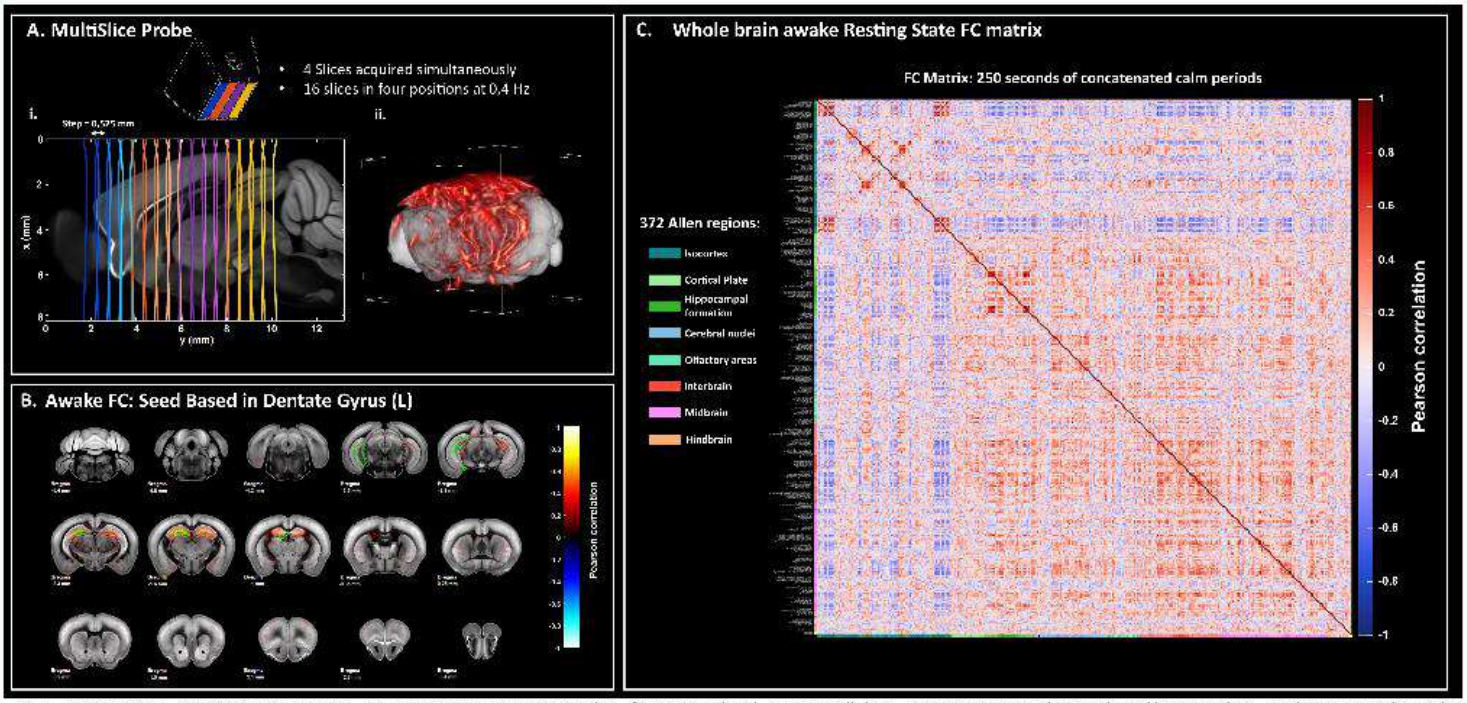
Functional Ultrasound (fUS) recently allowed 2D or 3D transcranial functional imaging in awake mice thanks to motorized linear or matrix arrays [1]. However, the tradeoff between the field of view and temporal resolution introduced by motorized scanning prevents acquiring whole-brain resting state Functional Connectivity (rsFC) whereas the limited sensitivity of matrix arrays prevents transcranial imaging in mice. Here we propose a new hybrid approach dedicated to 3D FC in the whole brain. A 15 MHz MultiArray probe was developed based on four high-sensitive compact linear arrays (4x64 transducers, pitch 110 µm, Iconeus, Paris, France), mounted on a 4-axis motor stage for automatic positioning and scanning both driven by the Iconeus One scanner. 3D rsFC was characterized in both anesthetized and head-fixed awake mice experiments. During rsFC acquisitions (20 minutes) the power Doppler was acquired in 4 slices simultaneously during 0.4s (200 compounded frames at 500 Hz) for four positions, resulting in 16 contiguous slices (525 µm step) acquired in 2.4s. After automatic atlas-based registration and preprocessing (temporal filtering, global mean regression), correlation matrices were computed with 372 Allen regions. Strong cortical and hippocampal bilateral connectivity patterns were found, and seed maps analysis allowed the quantification of long-ranged connectivity in the entire mouse brain. The MultiArray approach is a suitable solution for 3D functional imaging in awake and anesthetized mice without craniotomy. The wide field of view combined with the high sensitivity opens new opportunities to perform unbiased 3D functional connectivity measurements in the whole mouse

brain.



A.i. Principle of IcoPrime 4D MultiArray Probe: the four stacked arrays (blue, orange, purple and yellow color code) scanning the whole brain in four positions (represented with the color gradient) at a volume rate of 0.4 Hz. **ii. 3D Power Doppler angiography** registered on Allen Atlas. **B. Seed Based map (left Dentate Gyrus)** overlayed with the Allen two-photon template after Resting State FC experiment in awake mice, showing long ranged connectivity patterns. **C. Whole brain Resting State FC matrix in awake mice** computed on 250 s acquisituion and after automatic signal extraction in 372 volumic ROIs.

ACTIVITY ALTERATIONS OF VARIOUS BRAIN REGIONS IN ALCOHOL INTOXICATED DRIVERS: A SYSTEMATIC REVIEW AND META ANALYSIS OF FUNCTIONAL MAGNETIC RESONANCE IMAGING STUDIES

POSTER SESSION 06 - SECTION: FUNCTIONAL IMAGING OF THE BRAIN

Rasa Beheshti[1], Ali Norouzi[1], Sama Rahnemayan[2], Hossein Hosseinifard[3], Morteza Ghojazadeh[2], Alireza Lotfi[1]
[1]Tabriz University of Medical science, Student Research Committee, Tabriz, Iran, [2]Tabriz University of Medical science, Neuroscience Research Center, Tabriz, Iran, [3]Tabriz University of Medical science, Research Center For Evidence-based Medicine, Iranian Ebm Centre: A Joanna Briggs Institute Affiliated Group, Tabriz, Iran

Aim: Drunk driving is one of the main causes of traffic accidents. Years of functional magnetic resonance imaging (fMRI) research have revealed various effects of alcohol intoxication on drivers' brains, but there is no comprehensive summary of the exactly involved brain regions. Our aim was to conduct a meta-analysis to develop more effective intervention efforts for alcohol use disorder. **Methods:** Medline and other available databases were systematically searched to retrieve fMRI studies in the field of alcohol intoxication in drivers in comparison to non-intoxicated drivers. Articles were screened based on eligibility criteria. Meta-analysis was performed with the ALE method in GingerALE2.3.6 on MNI and Talairach coordinates from included studies. ALE maps were set at a threshold of $P<0.05$ and viewed with Mango software. **Results**: 4 articles were included in the meta-analysis. In comparison to non-inebriated drivers, ALE analysis revealed that alcohol-intoxicated drivers have significantly lower activation of the medial region of the right superior frontal gyrus, left thalamus, and left anterior cingulate gyrus. They also had higher activation in the right parietal operculum, right planum polare, right precentral gyrus, medial segment of right superior frontal gyrus, right superior frontal gyrus, left angular gyrus, left superior frontal gyrus, left superior motor cortex, and left superior frontal gyrus. **Conclusion**: This study is the first meta-analysis to offer key hyper- and hypo-activation regions of the brain while drunk driving. The obtained regional abnormalities in this study might serve as biomarkers to effectively understand the underlying brain mechanisms of impaired driving performance while intoxicated.

BRAIN TISSUE PULSATIONS (BTPS) IN ACUTE STROKE USING TRANSCRANIAL TISSUE DOPPLER TECHNIQUE (TCTD)

POSTER SESSION 06 - SECTION: FUNCTIONAL IMAGING OF THE BRAIN

Alanoud Almudayni[1], Emma Chung[2], Fatmah Alablani[1]
[1]University of Leicester, Cardiovascular Science Department, LEICESTER, United Kingdom, [2]King's College London, School Of Life Course And Population Science, London, United Kingdom

Aims: To investigate if brain tissue pulsations (BTPs) could be affected by the presence of acute stroke, and to explore the clinical potential of measuring BTPs using ultrasound in patients with ischaemic, haemorrhagic (ICH), and transient ischaemic attacks (TIA) compared to non-stroke control group. **Methods:** Recordings were obtained using a novel Transcranial Tissue Doppler (TCTD) technique. TCTD involves using a pair of 2 MHz ultrasound probes placed on the patient forehead. MATLAB software was used 'in house' for TCTD signal analysis, including bulk BTP amplitude, time to peak (TtP), and other physiological measurements. **Results:** BTPs were measured in 13 control subjects, 20 acute ischaemic stroke, 5 ICH patients and 12 TIA patients. A paired Wilcoxon signed rank test found no significant difference in bulk BTP amplitude and TtP between affected and unaffected hemispheres in stroke patients or between right and left sides for control subjects. A Kruskal-Wallis test found no significant differences in forehead combined bulk BTP amplitude and TtP between the control group and other groups (p = 0.06 and p = 0.43, respectively). Spearman's rank-order correlation test found a significant correlation between bulk BTP and MAP for ICH patients (r=1, p=0.01]. No association was found between bulk BTP amplitude and TtP with PP and MAP for other stroke patients. **Conclusion:** This study found no obvious disruptions to BTPs in patients with mild-moderate stroke. Overall, BTP amplitude and TtP seem unable to provide a good diagnostic indicator for stroke.

THREE-DIMENSIONAL VISUALIZATION OF CEREBRAL BLOOD VESSELS AND NEURAL CHANGES IN THICK ISCHEMIC RAT BRAIN SLICES USING TISSUE CLEARING

POSTER SESSION 06 - SECTION: FUNCTIONAL IMAGING OF THE BRAIN

Jongsoon Won
BINAREE, Laboratory, Daegu, Korea, Republic of

Blood vessels are structurally three-dimensional (3D) and precisely connected. Conventional histological methods are unsuitable for their analysis due to the destruction of the functionally important topological 3D vascular structures. Tissue optical clearing techniques allow extensive volume imaging and the analysis of vast information without destruction. This study applied a tissue clearing technique to acquire high-resolution 3D images of rat brain vasculature by light-sheet and confocal microscopies. The rat underwent middle cerebral artery occlusion for 45 min followed by 24 h reperfusion with lectin injected directly into the heart for vascular staining afterward. For the 3D images of vascular, 3-mm thick brain slices were reconstructed using tissue clearing and light-sheet microscopy. Subsequently, after 3D rendering, the fitting of blood vessels to a filament model was used for analysis. Therefore, this resulted in the vessel diameter and density in the ischemic region decreasing significantly compared to those with contralesional non-ischemic regions. Immunostaining of 0.5-mm thick brain slices showed considerable neuronal loss and increased fluorescence intensity of astrocytes in the ipsilateral region. Therefore, these methods can provide more accurate data by broadening the scope of the analyzed “Region of Interests” to study the 3D cerebrovascular system and observation of neuronal changes observed in various brain disorders.

CENTRIFUGATION-INDUCED HYPERGRAVITY, A NEW APPROACH TO MODULATE THE BLOOD-BRAIN BARRIER PERMEABILITY IN MICE?

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

David Dubayle[1], Arnaud Vanden-Bossche[2], Jean-Luc Morel[3]
[1]Université de Paris, Cnrs, Incc, Umr 8002, Paris, France, [2]Université Jean Monnet, Inserm, Sainbiose, U1059, Saint-Etienne, France, [3]Université de Bordeaux, Cnrs, Incia, Umr 5287, Bordeaux, France

Modifications of gravity levels induce generalized adaptation of mammalian physiology including vascular, brain, muscle, bone and immunity functions. It is known that centrifugation, increasing gravity level, affects the vestibular system and may be one of the sources of these physiological changes. As a crucial interface between the vascular system and the brain, the blood-brain barrier (BBB) acts as a filter to protect neurons from pathogens and inflammation. Our previous results suggested that centrifugation (24h, 2g) induce a BBB leakage in hippocampus measured by IgG extravasation (Dubayle et al., 2020). In order to characterize the opening size of BBB, we have performed i.v. injection of FITC-dextrans with different sizes (40, 70, 150 kDa). Their presences have been revealed directly in brain slices analyzed by microscopy (Nanozoomer). Currently, antisense oligonucleotides (ASON) are used to target specifically protein isoforms and reduce their expression. To be usable in neurosciences as therapeutical approaches ASON must pass throught the BBB (Boursereau et al., 2015). In the second part of this study, we have i.v. injected FAM-ASON (asANGPT2, 7kDa) and also analyzed by microscopy. We revealed fluorescent molecules in hippocampus, thalamus and cortex and also in liver as positive control organ. In conclusion, the crossing of BBB, from the blood to the brain parenchyma, depends on the size but also the nature of the molecules. Our experiences should be consolidated to validate centrifugation as non-invasive approach (i.v. administration) to increase delivery of pharmacological drug into the brain. **Keywords:** blood brain barrier, permeability, hypergravity, antisens oligonucleotide, dextran

Aims The aim of this study was to characterize the relations between mesencephalic regions (dlPAG) involved in cardiorespiratory control and their possible role in modulating laryngeal activity and their effects on vocalization. **Methods** Experimental studies were carried out with non-inbred male rats (n=14), SPF, Sprague-Dawley (250-300 g) housed under standard conditions. Animals were anesthetized with sodium pentobarbitone (60 mg/kg i.p., initial dose, supplemented 2 mg/ kg, i.v., as necessary). A double up and down tracheal cannulation was performed to measure subglottic pressure and airflow. Subglottic pressure was recorded with an aneroid transducer (Hugo Sachs Elektronik D-7801, ± 0,1 psi) by passing a stream of humidified warm medical air upwards with a thermal mass digital air flow meter controller (Bronkhorst Hi-Tec F-201CV-AGD-22-V). Bilateral parietostomy allowed access to dlPAG. Microinjections of PBS-Evans Blue (250 nl, pH 7.4 ± 0.1, 5-s duration) or glutamate (0,25M, 250 nl) were performed. Respiratory flow, pleural pressure, blood pressure, heart rate and ECG activity were also recorded. **Results** dlPAG PBS-Evans Blue microinjections did not produce any significant changes in any of the cardiorespiratory variables recorded. However, glutamate microinjections within the dlPAG evoked a decrease of laryngeal resistance (subglottal pressure) ($p<0,001$) accompanied with an inspiratory facilitatory response consisted of an increase in respiratory rate ($p<0,001$), together with a pressor ($p<0,05$) and tachycardic response ($p<0,001$). **Conclusions** The results of our study contribute with new data on the role of the mesencephalic neuronal circuits in the control mechanisms of subglottic pressure and laryngeal activity.

Pontine A5 region modulation of the cardiorespiratory response evoked from the midbrain dorsolateral periaqueductal grey. Connections between the midbrain dorsolateral periaqueductal grey (dlPAG) and the pontine A5 region have been shown. The stimulation of both regions evokes similar cardiovascular responses: tachycardia and hypertension. Accordingly, we have studied the interactions between dlPAG and A5 region in spontaneously breathing anesthetized rats. dlPAG was electrically stimulated (20-30 µA 1-ms pulses were given for 5 s at 100 Hz). Changes in the evoked cardiorespiratoy response were analysed before and after ipsilateral microinjections of muscimol (GABAergic agonist, 50 nl, 0.25 nmol, 5 s) within the A5 region. Electrical stimulation of the dlPAG produces, in the rat, a response characterized by tachypnoea ($p < 0.001$), hypertension ($p < 0.001$) and tachycardia ($p < 0.001$). The increase in respiratory rate was due to a decrease in expiratory time ($p < 0.01$). Pharmacological inhibition of the A5 region with muscimol produced a marked reduction of the tachycardia ($p < 0.001$) and the tachypnoea ($p < 0.01$) evoked from the dlPAG. Finally, to assess functional interactions between A5 and dlPAG, extracellular activity of putative A5 neurones were recorded during dlPAG electrical stimulation. Forty A5 cells were recorded, 16 of which were affected by dlPAG stimulation (40%). 4 cells showed activation, 5 cells excitation and 7 cells decreased spontaneous activity to dlPAG stimulation ($p < 0.001$). These results confirm a link between the A5 region and dlPAG. The potential role of these connections in the modulation of dlPAG evoked cardiorespiratory responses and their possible clinical implications are discussed.

SMALL EXTRACELLULAR VESICLES FROM PERIPHERAL BLOOD OF AGED MICE PASS THE BLOOD-BRAIN BARRIER AND INDUCE GLIAL CELL ACTIVATION

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

Akash Srivastava[1,2], Manja Marz[1,2]
[1]Leibniz Institute on Aging, Fritz Lipmann Institute (fli), Jena, Germany, [2]Friedrich Schiller University Jena, Rna Bioinformatics And High Throughput Analysis, Jena, Germany

Introduction: Extracellular vesicles (EVs), including small EVs (sEVs), are involved in neuroinflammation and neurodegenerative diseases, including Alzheimer's disease, Parkinson's disease, and amyotrophic lateral sclerosis. Yet, increased neuroinflammation can also be detected in the aging brain, and it is associated with increased glial activation. Changes in EV concentration are reported in aging tissues and senescence cells, suggesting a role of EVs in the process of aging. **Aims:** To investigate the effect of peripheral extracellular vesicles (EVs) from aged animals on neuroinflammation, specifically on glial activation. **Methods:** Extracellular vesicles (EVs) were isolated from the peripheral blood of young (3 months) and aged (24 months) C57BL/6J wildtype mice and injected into the peripheral blood from young animals via vein tail injections. The localization of EVs and the expression of selected genes involved in glial cell activation, including *Gfap*, *Tgf-β*, *Cd68*, and *Iba1*, were assessed in brain tissue 30 minutes, 4 hours, and 24 hours after injection. **Results:** We found that small EVs from peripheral blood of aged mice but not from young mice altered gene expression in the brains of young animals. In particular, the expression of the specific astrocyte marker, *Gfap*, was significantly increased, indicating a strong response of this glial cell type. **Conclusions:** Our study shows that small EVs from aged mice can pass the blood-brain barrier (BBB) and induce glial cell activation.

Age-dependent expression changes of circadian system-related genes reveal a potentially conserved link to aging.
The circadian clock system influences the biology of life by establishing circadian rhythms in organisms, tissues, and cells, thus regulating essential biological processes based on the day/night cycle. Circadian rhythms change over a lifetime due to maturation and aging, and disturbances in the control of the circadian system are associated with several age-related pathologies. However, the impact of chronobiology and the circadian system on healthy organ and tissue aging remains largely unknown. Whether aging-related changes of the circadian system's regulation follow a conserved pattern across different species and tissues, hence representing a common driving force of aging, is unclear. Based on a cross-sectional transcriptome analysis covering 329 RNA-Seq libraries, we provide indications that the circadian system is subjected to aging-related gene alterations shared between evolutionarily distinct species, such as , , , and . We discovered differentially expressed genes by comparing tissue-specific transcriptional profiles of mature, aged, and old-age individuals and report on six genes (, , , , , and) of the circadian system, which show conserved aging-related expression patterns in four organs of the species examined. Our results illustrate how the circadian system and aging might influence each other in various tissues over a long lifespan and conceptually complement previous studies tracking short-term diurnal and nocturnal gene expression oscillations.

Monocyte-Derived Macrophages Contribute to Chitinase Dysregulation in Amyotrophic Lateral Sclerosis: A Pilot Study.
Neuroinflammation significantly contributes to Amyotrophic Lateral Sclerosis (ALS) pathology. In lieu of this, reports of elevated chitinase levels in ALS are interesting, as they are established surrogate markers of a chronic inflammatory response. While post-mortem studies have indicated glial expression, the cellular sources for these moieties remain to be fully understood. Therefore, the objective of this pilot study was to examine whether the peripheral immune system also contributes to chitinase dysregulation in ALS. The temporal expression of CHIT1, CHI3L1, and CHI3L2 in non-polarized monocyte-derived macrophages (MoMas) from ALS patients and healthy controls (HCs) was examined. We demonstrate that while CHIT1 and CHI3L1 display similar temporal expression dynamics in both groups, profound between-group differences were noted for these targets at later time-points i.e., when cells were fully differentiated. CHIT1 and CHI3L1 expression were

significantly higher in MoMas from ALS patients at both the transcriptomic and protein level, with CHI3L1 levels also being influenced by age. Conversely, CHI3L2 expression was not influenced by disease state, culture duration, or age. Here, we demonstrate for the first time, that in ALS, circulating immune cells have an intrinsically augmented potential for chitinase production that may propagate chronic neuroinflammation, and how the ageing immune system itself contributes to neurodegeneration.

Tissue-specific Gene Expression Changes Are Associated with Aging in Mice.
Aging is a complex process that can be characterized by functional and cognitive decline in an individual. Aging can be assessed based on the functional capacity of vital organs and their intricate interactions with one another. Thus, the nature of aging can be described by focusing on a specific organ and an individual itself. However, to fully understand the complexity of aging, one must investigate not only a single tissue or biological process but also its complex interplay and interdependencies with other biological processes. Here, using RNA-seq, we monitored changes in the transcriptome during aging in four tissues (including brain, blood, skin and liver) in mice at 9 months, 15 months, and 24 months, with a final evaluation at the very old age of 30 months. We identified several genes and processes that were differentially regulated during aging in both tissue-dependent and tissue-independent manners. Most importantly, we found that the electron transport chain (ETC) of mitochondria was similarly affected at the transcriptome level in the four tissues during the aging process. We also identified the liver as the tissue showing the largest variety of differentially expressed genes (DEGs) over time. Lcn2 (Lipocalin-2) was found to be similarly regulated among all tissues, and its effect on longevity and survival was validated using its orthologue in Caenorhabditis elegans. Our study demonstrated that the molecular processes of aging are relatively subtle in their progress, and the aging process of every tissue depends on the tissue's specialized function and environment. Hence, individual gene or process alone cannot be described as the key of aging in the whole organism.

Conserved aging-related signatures of senescence and inflammation in different tissues and species.
Increasing evidence indicates that chronic inflammation and senescence are the cause of many severe age-related diseases, with both biological processes highly upregulated during aging. However, until now, it has remained unknown whether specific inflammation- or senescence-related genes exist that are common between different species or tissues. These potential markers of aging could help to identify possible targets for therapeutic interventions of aging-associated afflictions and might also deepen our understanding of the principal mechanisms of aging. With the objective of identifying such signatures of aging and tissue-specific aging markers, we analyzed a multitude of cross-sectional RNA-Seq data from four evolutionarily distinct species (human, mouse and two fish) and four different tissues (blood, brain, liver and skin). In at least three different species and three different tissues, we identified several genes that displayed similar expression patterns that might serve as potential aging markers. Additionally, we show that genes involved in aging-related processes tend to be tighter controlled in long-lived than in average-lived individuals. These observations hint at a general genetic level that affect an individual's life span. Altogether, this descriptive study contributes to a better understanding of common aging signatures as well as tissue-specific aging patterns and supplies the basis for further investigative age-related studies.

Transcriptional profiling reveals protective mechanisms in brains of long-lived mice.
The brain plays a central role in organismal aging but is itself most sensitive to aging-related functional impairments and pathologies. Insights into processes underlying brain aging are the basis to positively impact brain health. Using high-throughput RNA sequencing and quantitative polymerase chain reaction (PCR), we monitored cerebral gene expression in mice throughout their whole lifespan (2, 9, 15, 24, and 30 months). Differentially expressed genes were clustered in 6 characteristic temporal expression profiles, 3 of which revealed a distinct change between 24 and 30 months, the period when most mice die. Functional annotation of these genes indicated a participation in protection against cancer and oxidative stress. Specifically, the most enriched pathways for the differentially expressed genes with higher expression at 30 versus 24 months were found to be glutathione metabolism and chemokine signaling pathway, whereas those lower expressed were enriched in focal adhesion and pathways in cancer. We therefore conclude that brains of very old mice are protected from certain aspects of aging, in particular cancer, which might have an impact on organismal health and lifespan.

Ingenuity in pattern recognition: a novel bioinformatics approach towards lung cancer identification.
Lung cancer is the significant contributor of increased cancer deaths. Earlier research indicates that the environmental factors have a major role in causing lung cancer. It is evident that the pathway of lung cancer includes both RAS-mediated and non-

RAS-mediated mechanisms. Clinical findings point to a wide variety of other cancers contributing to lung cancer incidence. Such a scenario makes identification of lung cancer difficult and thus identifying its mechanisms can contribute to the society. Our study involves the RAS subfamily that includes a set of proteins, which cause an over expression of cancer-causing genes like M-ras and initiate tumour formation in lungs.

MIMICKING BLOOD BRAIN BARRIER IN MICROFLUIDIC MODELS

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

Cristina Staicu[1], Florin Jipa[1], Emanuel Axente[1], Daniel Banciu[2], Beatrice Radu[3], Felix Sima[1]
[1]National Institute for Laser, Plasma and Radiation Physics, Center For Advanced Laser Technologies, Magurele, Romania, [2]Politehnica University of Bucharest, Department Of Bioengineering And Biotechnology, Bucharest, Romania, [3]University of Bucharest, Department Of Anatomy, Animal Physiology And Biophysics, Bucharest, Romania

Aim: Blood brain barrier (BBB) is an extremely important structure for maintaining brain homeostasis. We thus aimed to reproduce appropriate physiological conditions by carrying out experiments in microfluidic lab-on-a-chip models that could mimic both architecture and functionality of BBB. One objective was to demonstrate biocompatibility of various transparent materials used for manufacturing the microfluidic devices with brain microvascular endothelial cells test them (bEnd.3 cell line) for mimicking BBB on a chip. **Methods:** For the fabrication of microfluidic networks in glass or polymeric substrates, we applied laser assisting etching methods to tailor material shape and physical characteristics. We then tested biocompatibility of the modified material surfaces by evaluation of actin fibres integrity and cytoskeleton with bEnd.3 cell line. Preliminary tests were also performed on microfluidic devices using human microvascular endothelial cells. For checking the BBB monolayer integrity, the ZO-1 tight junction proteins were immunostained and analysed by confocal fluorescence microscopy. **Results:** Our results have shown that most modified surfaces are biocompatible. The integrity of the BBB was demonstrated using optimized protocols for high-resolution microscopy visualization of the ZO-1 immunostained junction proteins. **Conclusions:** Our analyses have shown that various transparent materials modified by laser processing methods are suitable for BBB-on-a-chip studies. These materials were found appropriate to develop an adequate BBB model that will be further proposed as an *in vitro* tool for evaluating pathological conditions such as Alzheimer's disease and Parkinson's disease.

Lab-on-a-Chip Platforms as Tools for Drug Screening in Neuropathologies Associated with Blood-Brain Barrier Alterations.
Lab-on-a-chip (LOC) and organ-on-a-chip (OOC) devices are highly versatile platforms that enable miniaturization and advanced controlled laboratory functions (i.e., microfluidics, advanced optical or electrical recordings, high-throughput screening). The manufacturing advancements of LOCs/OOCs for biomedical applications and their current limitations are briefly discussed. Multiple studies have exploited the advantages of mimicking organs or tissues on a chip. Among these, we focused our attention on the brain-on-a-chip, blood-brain barrier (BBB)-on-a-chip, and neurovascular unit (NVU)-on-a-chip applications. Mainly, we review the latest developments of brain-on-a-chip, BBB-on-a-chip, and NVU-on-a-chip devices and their use as testing platforms for high-throughput pharmacological screening. In particular, we analyze the most important contributions of these studies in the field of neurodegenerative diseases and their relevance in translational personalized medicine.

Ca homeostasis in brain microvascular endothelial cells.
Blood brain barrier (BBB) is formed by the brain microvascular endothelial cells (BMVECs) lining the wall of brain capillaries. Its integrity is regulated by multiple mechanisms, including up/downregulation of tight junction proteins or adhesion molecules, altered Ca homeostasis, remodeling of cytoskeleton, that are confined at the level of BMVECs. Beside the contribution of BMVECs to BBB permeability changes, other cells, such as pericytes, astrocytes, microglia, leukocytes or neurons, etc. are also exerting direct or indirect modulatory effects on BBB. Alterations in BBB integrity play a key role in multiple brain pathologies, including neurological (e.g. epilepsy) and neurodegenerative disorders (e.g. Alzheimer's disease, Parkinson's disease, amyotrophic lateral sclerosis etc.). In this review, the principal Ca signaling pathways in brain microvascular endothelial cells are discussed and their contribution to BBB integrity is emphasized. Improving the knowledge of Ca homeostasis alterations in BMVECa is fundamental to identify new possible drug targets that diminish/prevent BBB permeabilization in neurological and neurodegenerative disorders.

Altered Organelle Calcium Transport in Ovarian Physiology and Cancer.
Calcium levels have a huge impact on the physiology of the female reproductive system, in particular, of the ovaries. Cytosolic calcium levels are influenced by regulatory proteins (i.e., ion channels and pumps) localized in the plasmalemma and/or in the endomembranes of membrane-bound organelles. Imbalances between plasma membrane and organelle-based mechanisms for calcium regulation in different ovarian cell subtypes are contributing to ovarian pathologies, including ovarian cancer. In this review, we focused our attention on altered calcium transport and its role as a contributor to tumor progression in ovarian cancer. The most important proteins described as contributing to ovarian cancer progression are inositol trisphosphate receptors, ryanodine receptors, transient receptor potential channels, calcium ATPases, hormone receptors, G-protein-coupled receptors, and/or mitochondrial calcium uniporters. The involvement of mitochondrial and/or endoplasmic reticulum calcium imbalance in the development of resistance to chemotherapeutic drugs in ovarian cancer is also discussed, since Ca channels and/or pumps are nowadays regarded as potential therapeutic targets and are even correlated with prognosis.

Role of microRNAs as Clinical Cancer Biomarkers for Ovarian Cancer: A Short Overview.
Ovarian cancer has the highest mortality rate among gynecological cancers. Early clinical signs are missing and there is an urgent need to establish early diagnosis biomarkers. MicroRNAs are promising biomarkers in this respect. In this paper, we review the most recent advances regarding the alterations of microRNAs in ovarian cancer. We have briefly described the contribution of miRNAs in the mechanisms of ovarian cancer invasion, metastasis, and chemotherapy sensitivity. We have also summarized the alterations underwent by microRNAs in solid ovarian tumors, in animal models for ovarian cancer, and in various ovarian cancer cell lines as compared to previous reviews that were only focused the circulating microRNAs as biomarkers. In this context, we consider that the biomarker screening should not be limited to circulating microRNAs per se, but rather to the simultaneous detection of the same microRNA alteration in solid tumors, in order to understand the differences between the detection of nucleic acids in early vs. late stages of cancer. Moreover, in vitro and in vivo models should also validate these microRNAs, which could be very helpful as preclinical testing platforms for pharmacological and/or molecular genetic approaches targeting microRNAs. The enormous quantity of data produced by preclinical and clinical studies regarding the role of microRNAs that act synergistically in tumorigenesis mechanisms that are associated with ovarian cancer subtypes, should be gathered, integrated, and compared by adequate methods, including molecular clustering. In this respect, molecular clustering analysis should contribute to the discovery of best biomarkers-based microRNAs assays that will enable rapid, efficient, and cost-effective detection of ovarian cancer in early stages. In conclusion, identifying the appropriate microRNAs as clinical biomarkers in ovarian cancer might improve the life quality of patients.

INVESTIGATING THE EXPRESSION AND FUNCTIONAL ROLE OF KV7 CHANNELS IN BRAIN ENDOTHELIAL CELLS

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

Vincenzo Barrese, Lidia Carotenuto, Francesco Miceli, Maurizio Taglialatela
University of Naples Federico II, Neuroscience, Napoli, Italy

The blood-brain barrier (BBB) protects brain parenchyma from neurotoxic agents and regulates the composition of the brain interstitial fluid that is crucial for the proper functioning of neurons. Such properties are determined by the presence of tight junctions (TJs) between brain endothelial cells (ECs) that limit the paracellular flow of ions and solutes, and by specific transporters and ion channels expressed in EC. Whilst solute transporters in ECs have been thoroughly studied, the role of ion channels have been poorly investigated. In this study we evaluated the expression and the function of the five members of the voltage-gated Kv7 potassium channels family in *in vitro* models of BBB. Quantitative PCR (Q-PCR) and immunofluorescence experiments showed the expression of Kv7.1, Kv7.4 and Kv7.5 in clonal ECs (BEND cells), brain microvessels (BMVs), and primary ECs, with Kv7.5 being localized at cell-cell junction sites; instead, the expression of Kv7.2 and Kv7.3 was negligible. In BMVs, Kv7.4 was also expressed in pericytes that, along with astrocytes, form the neurovascular unit. In BEND cells cultured in Transwell inserts, pharmacological activation of Kv7 channels with the specific opener retigabine (10 μM) reduced paracellular flux of fluorescent dextran; this effect was prevented by the selective Kv7 blocker XE-991 (10 μM). Immunofluorescence experiments using a TJ-specific marker (Zonula Occludens-1) revealed that retigabine also reduced the number of breaks in the continuity of TJs between ECs. Overall, these results show that Kv7 channels are expressed in brain ECs, and suggest that their pharmacological modulation regulates BBB permeability.

THE HIGHLY REACTIVE DICARBONYL COMPOUND, METHYLGLYOXAL, REGULATES THE PURINERGIC SIGNALING PATHWAYS IN BRAIN ENDOTHELIUM

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

Roberta Stoica[1,2], Calin Rusu[3], Mihai Radu[2], Beatrice Radu[3]
[1]Faculty of Biology, University of Bucharest, Doctoral School Of Biology, Bucharest, Romania, [2]Horia Hulubei National Institute for Physics and Nuclear Engineering, Life And Environmental Physics, Magurele, Romania, [3]University of Bucharest, Department Of Anatomy, Animal Physiology And Biophysics, Bucharest, Romania

Aim: Inducing oxidative stress in the endothelium of brain vasculature can lead to DNA damage, increase the intracellular calcium concentration, cell death. Considering the major role of blood-brain barrier (BBB) to ensure cerebral homeostasis, the goal of this study is to understand the murine cerebral microvasculature endothelial cells behavior after 24 hours' exposure to methylglyoxal (MGO), known for its ability to generate reactive oxygen species (ROS). Methods: Murine brain microvasculature endothelial cells, bEnd.3 cell line, were exposed to MGO (1-1000 µM) and tested for the cellular viability (MTT assay), cellular response to ATP (calcium imaging assay) and ROS production. Specific inhibitors for the purinergic signaling pathway: phospholipase C inhibitor (U73122), inositol-triphosphate receptor inhibitor (2-APB) and P2Y2 receptor inhibitor (ARC 118925XX) were used to modulate the MGO effect. Results: High concentrations of methylglyoxal (over 250 µM) significantly enhanced ROS production (5-10 times) and diminished cellular viability (down to 40% for 1000 µM MGO). The ATP response was tested in the range of 0-250 µM MGO where no significant change in viability and ROS production was observed. Exposure to MGO induced a stimulatory effect on the amplitude (~50%) and area (~50%) of the calcium transient accompanied by a reduction of its latency (~50%). The inhibitors used in these experiments modulated the effects induced by MGO treatment. Conclusions: We demonstrated that MGO modulates the purinergic signaling pathway in brain microvascular endothelium. These results are relevant in understanding the BBB behavior in glycation and oxidative stress conditions associated to various neuropathologies.

Endothelial cells (ECs) in cerebral vessels are a primary target for acute brain injury and the dysfunction of ECs leads to secondary inflammatory injury through blood-brain barrier (BBB) disruption. Although quality control of BBB is important to prevent acute brain injury, modulatory signaling of it still needs further investigation. According to our previous report, the defect of mitochondrial respiration in ECs leads to profound BBB disruption but the downstream signaling pathway was not revealed. To identify the link between a mitochondrial defect in ECs and BBB disruption, we isolated cerebral vessels from TEKCRIF1 mouse and performed RNA sequencing. 908 (p-value 0.05) differentially expressed genes were identified. Among the candidate signaling from transcriptome analysis, we focused on the Notch1 signaling which closely correlated to BBB maintenance. With the intracerebral hemorrhage (ICH) mouse model, we observed the decrease of Notch1 signaling and mitochondrial OxPhos complex expression that results in BBB disruption. To assess the function of Notch1 signaling in BBB disruption, we injected an agonist of Notch1 receptor into the ICH mouse model. With the treatment, we found the prevention of BBB disruption and decrease of injury area of ICH model accompanying alteration of mitochondrial OxPhos complex. Taken together, we suggest that activation of Notch1 signaling could be prevention of acute brain injury through quality control of BBB, and one of the modulatory signaling between mitochondrial defect and BBB disruption.

MICROGLIA SHAPE A GENETIC CEREBRAL SMALL VESSEL DISEASE

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

Ümit Özorhan[1], Josephine Lampe[1], Yun Jiang[2], Markus Schwaninger[1]
[1]University of Lübeck, Institute Of Experimental And Clinical Pharmacology And Toxicology, Lübeck, Germany, [2]University of Marburg, Pharmacology, Marburg, Germany

Cerebral small vessel diseases are a common source of disability. While most cases are sporadic, genetic forms provide insight into the cellular and molecular mechanisms underlying the vessel pathology. Mutations in the *NEMO* gene are the cause of incontinentia pigmenti (IP) that is associated with a cerebral small vessel disease. To model IP, we deleted *Nemo* in the brain endothelial cells of mice ($Nemo^{beKO}$). In addition to the known loss of brain capillaries, we found an increase in the number of microglia in the brains of $Nemo^{beKO}$ mice. To explore their function, we ablated microglia by feeding mice a PLX-5622 containing diet. Ablation of microglia improved the anxiety-like phenotype of mice in the open field and lowered the seizure threshold as determined by maximal electroshocks. In parallel, the number of remnant dead capillaries, so-called string vessels, and of activated astrocytes slightly increased. In summary, microglia aggravate the functional consequences of a small vessel disease. Interfering with microglia activation may represent a strategy to treat cerebral small vessel diseases.

BRAIN ENDOTHELIAL GαQ/11 KNOCKOUT INDUCES SYSTEMIC METABOLIC CHANGES

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

Dorothea Ziemens, Marius Richter, Nina Feller, Helge Müller-Fielitz, Markus Schwaninger, Jan Wenzel
University of Lübeck, Institute Of Experimental And Clinical Pharmacology And Toxicology, Lübeck, Germany

Cerebral endothelial dysfunction refers to the loss of physiological properties and functionality of the brain endothelium. The impaired reactivity of the vasculature leads to an insufficient supply of energy substrates like glucose and insufficient removal of molecules such as carbon dioxide (CO_2) from the brain tissue. CO_2 is a well-known metabolic end product of cellular metabolism and has effects on brain areas that control essential functions such as respiration. Recently, CO_2-sensitive neurons have also been described in brain areas relevant to energy homeostasis. The extent to which endothelial dysfunction and its consequences like impaired CO_2 removal contribute to the development of metabolic changes remains unknown. To this purpose, we developed a mouse model mimicking cerebral endothelial dysfunction that is induced by a knockout of the $G\alpha_{q/11}$ signalling pathway specifically in brain endothelial cells ($G\alpha_{q/11}^{beKO}$ mice). These mice show a loss of vascular reactivity to stimuli such as CO_2. Mice were examined for energy metabolism in a basal and diet-induced obese state. We could show that under basal conditions, $G\alpha_{q/11}^{beKO}$ mice show differences in body composition compared to control mice, and along with that, we found an impaired glucose metabolism by using different measurements. Under the influence of a high-fat diet, $G\alpha_{q/11}^{beKO}$ mice showed a decrease and dampened circadian rhythmicity. With our experiments, we obtained strong evidence for the influence of an impaired vascular reactivity in the brain on the peripheral metabolism. Our findings suggest a link between cerebral endothelial dysfunction and the outcome and progression of diet-induced obesity.

[1]University of Copenhagen, Department Of Neuroscience, Copenhagen, Denmark, [2]Rigshospitalet, Department Of Clinical Biochemistry, Copenhagen, Denmark, [3]University of Copenhagen, Department Of Biomedical Sciences, Copenhagen, Denmark, [4]The Neuroscience Centre, Rigshospitalet Glostrup, University of Copenhagen, Department Of Clinical Neurophysiology, Glostrup, Denmark

Background: Aging, stroke, and chronic brain disorders are accompanied by neurotoxic increases in adsorptive-mediated transcytosis (AMT), a non-specific transport of proteins across the blood-brain barrier (BBB). We have shown that impairment of sphingosine-1-phosphate receptor 1 (S1PR1) signaling at the BBB leads to detrimental increases in AMT. Two features stood out: only arterioles were affected, and the BBB could be rapidly rescued by selective S1PR1 agonism. However, the mechanisms remained unknown. **Hypothesis:** Glycocalyx is a meshwork of glycoproteins and proteoglycans, constituting a non-cellular component of the BBB. Negatively-charged glycocalyx lines the luminal side of the endothelial cells and can putatively repel plasma proteins from entering AMT. We hypothesized that S1PR1 signaling impairment causes glycocalyx loss, which might explain AMT increase. **Methods:** Glycocalyx is seldom preserved *ex vivo*. Therefore; a) we used two-photon microscopy (2PM) to image BBB in mice with impaired S1PR1 signaling (*Apom*$^{-/-}$mice); and b) we developed a 2PM photobleaching approach to quantify the extent of glycocalyx changes at different categories of cerebral microvessels, i.e., arterioles, capillaries, and venules *in vivo.* **We show that:** (i) S1PR1 signaling impairment led to glycocalyx loss; and exclusively in arterioles, which mirrored the vascular zonation of AMT increase; (ii) S1PR1 stimulation that was sufficient to rapidly rescue AMT (<150 min) did not reinstate the glycocalyx within the same time frame; (iii) Glycocalyx recovery occurred much later, over days, and upon recurrent agonism of S1PR1. **Conclusions:** Glycocalyx loss may contribute to AMT increase, but the reconstitution of the glycocalyx is not critical to normalizing AMT.

APPROACHING IN-VIVO BBB PERMEABILITIES WITH ENGINEERED BLOOD-BRAIN BARRIER-ON-CHIP

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

Tuan Nguyen[1], Tuuli-Maria Sonninen[2], Sarka Lehtonen[2], Prateek Singh[3]
[1]University of Oulu, Faculty Of Biochemistry And Molecular Medicine, Oulu, Finland, [2]University of Eastern Finland, Faculty Of Health Sciences, Kuopio, Finland, [3]Finnadvance, Microfluidics And Microtechnology Solutions, Oulu, Finland

Accurate modeling of the Blood-Brain Barrier (BBB) is crucial in maintaining brain homeostasis and is the key barrier to understanding drug pharmacokinetics.

Our microfluidic BBB-on-chip platform design includes static conditions of the brain-side of the BBB, as well as the dynamic conditions of the brain microvasculature within the same platform, mimicking in-vivo conditions. Our BBB-on-chip is established using a co-culture of endothelial cells and astrocytes, cultured on opposing sides of a semipermeable membrane. The confluence of cell layers is achieved approximately after 7 days of culture when the barrier properties are validated.

In-vitro BBB generated with either mono or cultured brain endothelial cells and astrocytes showed marked improvement in Papp (apparent permeabilities) when cultured under the flow conditions. Mouse BBB-on-chip showed a Papp for 70 kDa Dextran to be 1.7E-7 cm/s, which is astonishingly close to in-vivo observed Papp of 1.5E-7 cm/s.

We have demonstrated that flow shear stress and dynamic flow conditions are crucial for improving in-vitro BBB permeabilities. Our microfluidic BBB model accurately reflects the in vivo conditions of the BBB by modeling both the static conditions of the brain-side of the BBB, as well as the dynamic conditions of the brain microvasculature within the same platform. As the highest-throughput platform currently in the field, our BBB model enables the development and screening of new therapeutics for neurological disorders still lacking effective treatments, such as Alzheimer's and Parkinson's disease.

Low-Cost, Accessible Fabrication Methods for Microfluidics Research in Low-Resource Settings.
Microfluidics are expected to revolutionize the healthcare industry especially in developing countries since it would bring portable, easy-to-use, self-contained diagnostic devices to places with limited access to healthcare. To date, however, microfluidics has not yet been able to live up to these expectations. One non-negligible factor can be attributed to inaccessible prototyping methods for researchers in low-resource settings who are unable to afford expensive equipment and/or obtain critical reagents and, therefore, unable to engage and contribute to microfluidics research. In this paper, we present methods to create microfluidic devices that reduce initial costs from hundreds of thousands of dollars to about $6000 by using readily accessible consumables and inexpensive equipment. By including the scientific community most embedded and aware of the requirements of healthcare in developing countries, microfluidics will be able to increase its reach in the research community and be better informed to provide relevant solutions to global healthcare challenges.

EFFECT OF AGEING ON THE CEREBRAL HEMODYNAMICS IN THE MARMOSET MONKEY

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

Caroline Fonta[1], Germain Arribarat[1], Muriel Mescam[1], Franck Desmoulin[2]
[1]CerCo (Brain and Cognition Research Center), Cnrs -university Of Toulouse, Toulouse, France, [2]INSERM, Tonic, Toulouse, France

Aim Cerebrovascular function declines during normal ageing and appears to be closely linked to brain function alteration in the elderly. We adapted dedicated MRI sequences to analyze blood flow dynamics in arterial and venous intracranial vessels, using a non-human primate model of significant interest for preclinical research, the marmoset monkey *Callithrix jacchus*. **Methods** Imaging sequences were acquired on a 7T MRI (Bruker Biospec, voxel size: 0,15x0,15X1mm3) on two groups of male and female marmosets: 10 young (4 years old) and 9 aged (9 years old). Internal carotid arteries, basilar artery, superior and inferior sagittal sinuses were first identified by Time Of Flight (TOF) sequences and flow velocity in these different vessels was recorded by Phase Contrast (PC) MRI synchronized with ECG signal. **Results** The main significant results show that during the cardiac cycle: -The blood flow peaks earlier in the basilary trunk than in the carotids. -The arterial flow peak occurs earlier in the aged than in the young marmoset brains. -The time interval between the arterial- and the venous flow peaks is shorter in old than in young marmosets. **Conclusions** These results reflect vessel rigidity and tissue compliance changes occurring during ageing in the vascular network. They have not been shown in human studies, in which blood flow dynamics are usually synchronized with peripheral pulse measured on the fingertip. They suggest that the time courses of the different vascular flows could contribute as early markers of brain ageing and brain pathologies. ***Supported by ANR Hanuman 18-CE45-0014-01***

CEREBROVASCULAR REACTIVITY TO HYPERCAPNIA AND NEUROVASCULAR COUPLING EXPLORE DIFFERENT VASCULAR BEDS

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

Marine Tournissac[1,2], Ali-Kemal Aydin[1], Yannick Goulam Houssen[1], Davide Boido[3], Emmanuelle Chaigneau[1], Anne Joutel[2], Serge Charpak[1]
[1]Sorbonne université, Vision Institute, Paris, France, [2]Université Paris Cité, Institute Of Psychiatry And Neuroscience Of Paris, Paris, France, [3]Neurospin, Cea Saclay, Gif-Sur-Yvette, France

Background: Cerebrovascular reactivity (CVR) to hypercapnia is the gold standard to evaluate vascular diseases with BOLD fMRI. In contrast to neurovascular coupling, the spatial and temporal dynamics of cellular and vascular responses to CO_2 along the vascular arbor remain unclear. **Aim:** Our goal was to investigate and compare the dynamics of CVR and neurovascular coupling along the vascular arbor in the mouse barrel cortex. **Methods:** Using two-photon imaging in sedated mice, implanted with a chronic cranial window, we measured vascular and cellular responses (pyramidal cells, smooth muscle cells, pericytes, endothelial cells and astrocytes expressing GCaMP6) to CO_2 (20%, 10 s) and whisker stimulations from pial arterioles to veins. **Results:** As previously reported, whisker stimulation triggered fast activation of neurons and smooth muscle cells, followed within ~1 s by dilation of penetrating arterioles and systematic increases of blood velocity in downstream capillaries and veins. In contrast, CO_2 stimulation generated a different sequence of events: in pial and penetrating arterioles, CO_2 triggered an initial velocity decrease, a 4 s delayed Ca^{2+} drop in smooth muscle cells, a further delayed dilation and blood flow increase (7 and 13 s, respectively). At the level of capillaries, the effect of CO_2 was sparse and small. In opposition to other cells of the neurovascular unit, pyramidal cell activity was not affected by CO_2. **Conclusions:** Overall, our data suggest that CVR to hypercapnia reports mostly the function of large arteriolar vessels whereas neurovascular coupling investigates the function of the entire neurovascular unit.

MEASUREMENT OF BLOOD FLOW VELOCITY WITH LASER SCANNING MICROSCOPY: MODELLING AND COMPARISON OF LINE-SCAN IMAGE-PROCESSING ALGORITHMS.

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

Emmanuelle Chaigneau, Serge Charpak
Institut de la Vision, Sorbonne Université, Inserm U968, Cnrs Umr 7210, Paris, France

Aim: Blood flow is commonly monitored to follow brain activity. At the cellular level, laser scanning microscopy is the technique of choice to measure blood velocity with line-scans and compare data sets across animal models and experimental conditions. Although velocity differences as low as a few percent have been reported, the extent to which measurements depend on the choice of experimental parameters and the image analysis is too often ignored. We have previously shown how to suppress the errors resulting from scanning by providing an unbiased algorithm to calculate velocities. Here, we investigated the errors resulting from the interplay of acquisition parameters and image-analysis algorithms. Methods: Analysis of blood flow velocity from line-scans requires specific image-processing algorithms, such as angle measurements, Line-Scanning Particle Image Velocimetry or Fourier transformation of line-scan images. We developed mathematical models for each of them. We also provide a software generating artificial line-scan images to test the models. Results: Our models predict the experimental conditions under which each image-processing algorithm gives velocity measurements with a given accuracy. We apply our approach to different vessel types and give the parameter space available for each image-processing algorithm. We validate our models with artificial line-scans. Conclusion: Our study provides efficient tools to the community of vascular physiologists and imaging neuroscientists that monitor blood flow changes to assess normal and pathological brain function.

MODELING THE RELATION BETWEEN NEURONAL ACTIVITY AND THE BOLD SIGNAL VIA ASTROCYTIC CALCIUM DYNAMICS

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

Federico Tesler[1], Marja-Leena Linne[2], Alain Destexhe[1]
[1]Université Paris-Saclay - NeuroPsi (CNRS), Integrative & Computational Neuroscience (icn), Saclay, France, [2]Tampere University, Faculty Of Medicine And Health Technology, Tampere, Finland

Functional magnetic resonance imaging (fMRI) relies on the coupling between neuronal and vascular activity, but the mechanisms behind this coupling are still under discussion. Recent experimental evidence suggests that calcium signaling may play a significant role in neurovascular coupling. However, it is still controversial where this calcium signal is located (in neurons or elsewhere), how it operates and how relevant is its role. In this work we introduce a biologically plausible model of the neurovascular coupling and we show that calcium signaling in astrocytes can explain the main aspects of the dynamics of the coupling. We find that calcium signaling can explain so-far unrelated features such as the linear and non-linear regimes, the negative vascular response (undershoot) and the emergence of a (calcium-driven) Hemodynamic Response Function. We analyze how information is coded and transmitted from the neuronal to the vascular system and we find that frequency modulation of astrocytic calcium dynamics plays a key role in this process. Our work provides a framework to link neuronal activity to the BOLD signal, and vice-versa, where neuronal activity can be inferred from the BOLD signal. This opens new ways to link known alterations of astrocytic calcium signaling in neurodegenerative diseases (e.g. Alzheimer's and Parkinson's diseases) with detectable changes in neurovascular coupling. Finally, in our modeling framework the neuronal-astrocyte pathway is built upon a mean-field description of neuronal activity, which makes it suitable for its implementation in large-scale simulations. We show an example of such an implementation for whole-brain simulations.

Although great efforts to characterize the embryonic phase of brain vascular system development have been made, its postnatal maturation has barely been described. Here, we compared the molecular and functional properties of brain vascular cells on postnatal day (P)5 vs. P15, via a transcriptomic analysis of purified mouse cortical microvessels (MVs) and the identification of vascular-cell-type-specific or -preferentially expressed transcripts. We found that endothelial cells (EC), vascular smooth muscle cells (VSMC) and fibroblasts (FB) follow specific molecular and functional maturation programs over this time period. In particular, ECs acquire P-glycoprotein (P-gP)-mediated efflux capacities. The arterial VSMC network expands and becomes contractile resulting in a greater cerebral blood flow (CBF). Samples of human brain cortex showed the same postnatal maturation process. Thus, the early postnatal phase is a critical period during which essential properties of cerebral blood vessels, i.e. the endothelial efflux of xenobiotics and other molecules, and the VSMC contractility required for vessel tone and brain perfusion, are acquired and mature.

CHARACTERIZING THE OXYGEN INITIAL DIP IN THE BRAIN OF ANESTHETIZED AND AWAKE MICE

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

Ali-Kemal Aydin
Inserm, Vision Institute, Paris, France

Background: An ongoing controversy in brain metabolism and imaging based on deoxyhemoglobin detection is whether increases in neural activity cause a local and rapid decrease in oxygen concentration (the "Po_2 initial dip") preceding functional hyperemia. Here, we reinvestigated the issue by targeting a distinct neuronal network in the olfactory bulb, the glomerulus most sensitive to ethyl tiglate (GMS_{ET}) and a site of strong activation and energy consumption upon ET stimulation. **Aim:** Our goal was to determine the experiment conditions under which a Po_2 initial dip is detected near activated synapses, in the neuropil and in capillaries. **Method:** Using two-photon fluorescence and phosphorescence lifetime imaging in Thy1-GCaMP6 mice implanted with a cranial window for more than 2 weeks, we measured vascular and tissue Po_2 with the oxygen sensor Oxyphor 2P, simultaneously with neuronal calcium signals in the GMS_{ET}. Measurements were performed in mice anesthetized (Ketamine/Domitor) and awake. **Results/Conclusions:** In anesthetized mice, a transient dip in vascular Po_2 was detected in the GMS_{ET} when functional hyperemia was slightly delayed, but its amplitude was minute. The vascular Po_2 dip was not observed in glomeruli responding non-specifically to ET and was poorly influenced by resting Po_2. In awake mice, this dip in Po_2 was absent in capillaries as well as, surprisingly, in the neuropil. This demonstrates that in awake mice recovered from brain surgery, neurovascular coupling is too fast and efficient to reveal any dip in Po_2.

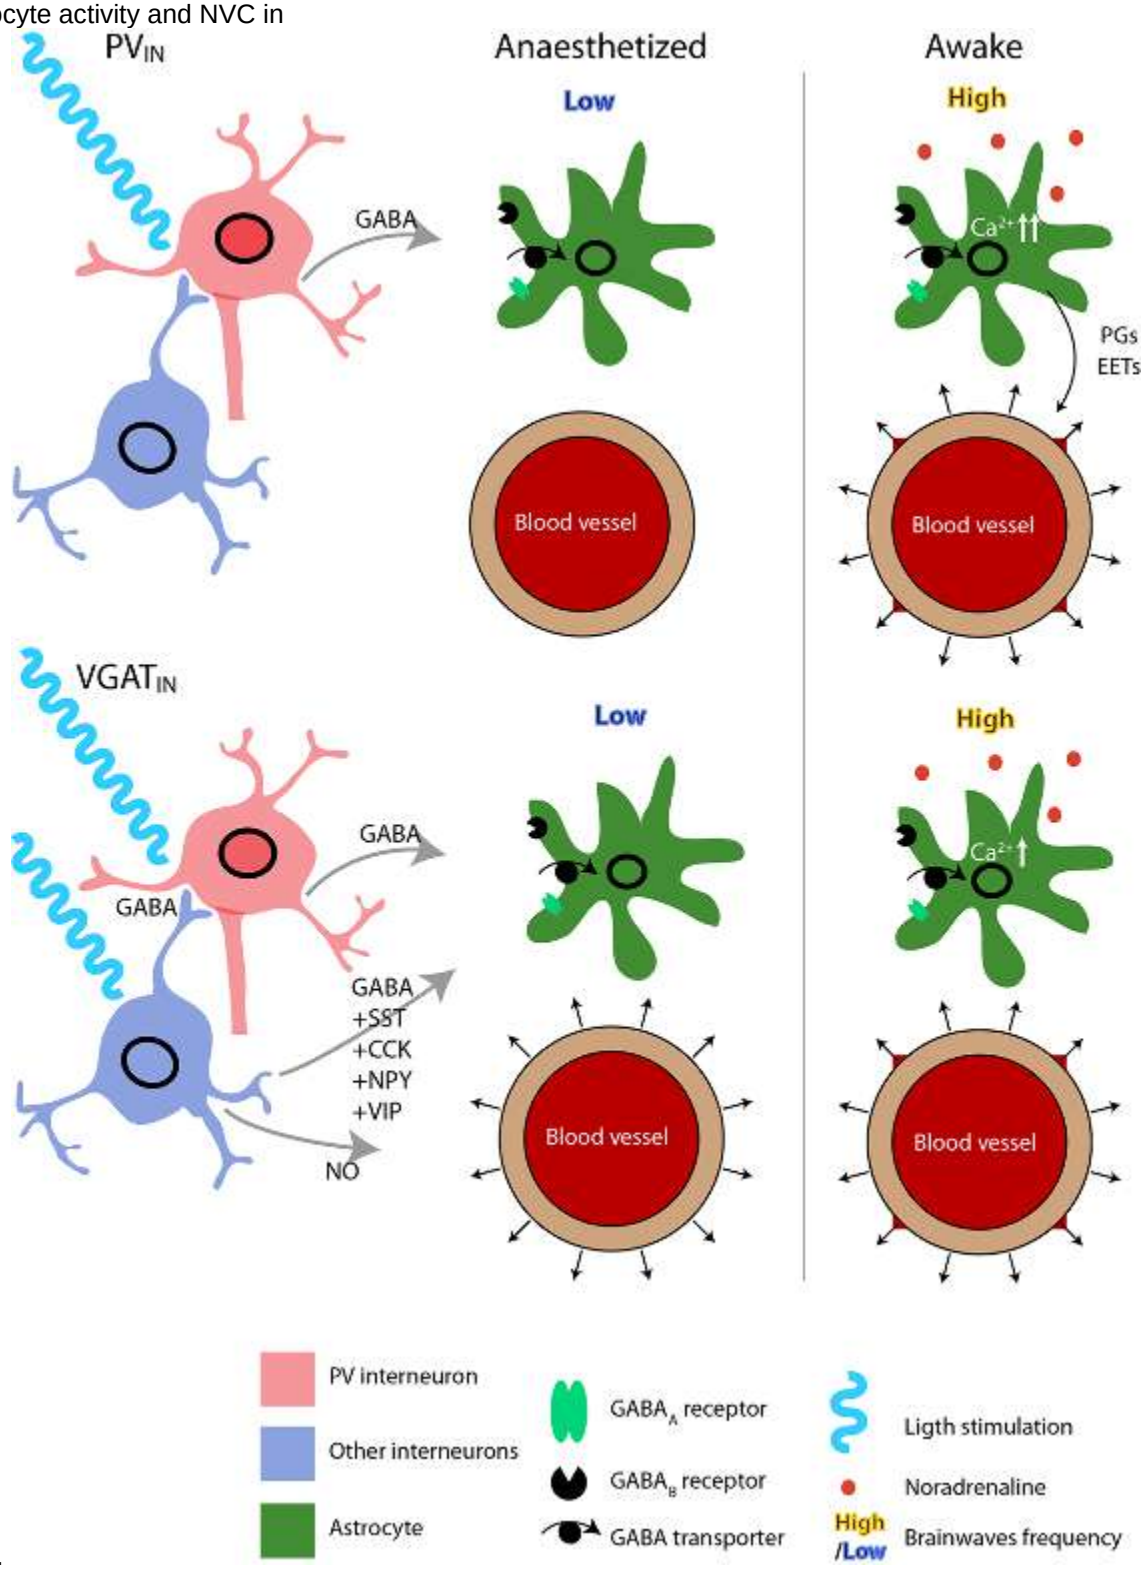
ASTROCYTIC CA2+ SIGNALS PARTAKE IN INHIBITORY NEUROVASCULAR COUPLING IN A BRAIN STATE-DEPENDENT MANNER.

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

Barbara Lind
University of Copenhagen, Department Of Neuroscience, Copenhagen, Denmark

Neurovascular coupling (NVC) modulates cerebral blood flow to match increased metabolic demand during neuronal excitation. Activation of inhibitory interneurons also increase blood flow, but the basis for this inhibitory NVC is unclear. We performed two-photon microscopy in awake mice to examine the correlation between astrocytic Ca^{2+} and NVC, evoked by activity in either all ($VGAT_{IN}$) or parvalbumin-positive GABAergic interneurons (PV_{IN}). Optogenetic stimulation of $VGAT_{IN}$ and PV_{IN} in the somatosensory cortex triggered astrocytic Ca^{2+} increases that were abolished by anaesthesia. PV_{IN} evoked astrocytic Ca^{2+} responses with a short latency that preceded NVC, whereas $VGAT_{IN}$ evoked Ca^{2+} increases that were delayed relative to the NVC response. The early onset in PV_{IN} evoked Ca^{2+} increases dependent on noradrenaline release from locus coeruleus, which also affected inhibitory NVC. Therefore, inhibitory NVC mechanisms should be studied in awake mice and, though the relationship between interneuron activity and astrocytic Ca^{2+} is complex, there is a correlation between

astrocyte activity and NVC in



PV$_{IN}$.

The brain is densely perfused by the vascular network, which provides nutrients and oxygen to support neuronal function. The architecture of the cerebral vasculature addresses specific constrains of the neural tissues, including the near absence of energy storage and very high metabolic demand. Despite the clear observation that both the vascular density and the metabolic demands are heterogenous across the brain, whether and how neuronal activity controls the vascular topology is still debated for several reasons: first, there is no correlation between the densities of neurons and blood vessels. Second, the organization of the vascular and neuronal networks don’t match closely. Third, there is disagreement in the literature on whether modulating neuronal activity levels can lead to a remodeling of the vasculature or not. To better understand the relationship between the metabolic need of the different neural cell types and the topology of the adult vascular network, we built a 3D developmental atlas of the brain vasculature. For this, we generated the annotation maps and templates for the developing mouse brain to align vascular datasets onto. We next optimized a series of computational tools to measure and classify the organization of the different brain regions. We used these tools to generate developmental trajectories for the various brain regions and tested how a lack of neuronal activity affects their developmental. This work also revealed how the vascular network can cater differently to the metabolic needs of both the developing and adult brain.

Aims. Organophosphate (OP) compounds are highly toxic chemicals widely used as pesticides, but also as chemical warfare nerve agent (NA). The incidence of accidental poisoning with OP pesticides is associated with nearly 100,000 annual deaths worldwide for 2 million reported cases of intoxication. More worryingly, the use of neurotoxic weapons demonstrates the ever-persistent threat. NA exposure leads to the irreversible inhibition of cholinesterases, affecting both the peripheral and the central nervous system (CNS). In the CNS, if the cholinergic hyperactivity is not quickly stopped, it will lead to seizure and epileptic activity that will induce brain damages, neuronal degeneration, BBB dysfunction, cerebral edema and significant neuroinflammation. However, the effects of NA on the neurovascular system remain poorly understood. This work aimed to explore anatomical and functional neurovascular consequences of an exposure of a sarin surrogate (NIMP). **Methods**. For that purpose, MRI molecular imaging of the adhesion molecules (VCAM-1) was used to uncover neurovascular inflammation *in vivo* after 2 different sublethal doses of a sarin analog exposition (0.5LD50 and 0.9LD50). Functional consequences were measured on the somatosensory cortex using speckle contrast imaging. **Results**. We demonstrate that cerebrovascular inflammation was already perceptible 6 hours after exposure up to 7 days for the highest dose. Neurovascular coupling was altered up to 1 month after NIMP exposure whatever the dose as shown by speckle imaging. **Conclusions.** This method allows to detect neurovascular inflammation after mild OP exposure which would improve the diagnosis and management of patients to avoid long-term cerebral impact.

HUMAN IPSC-BASED MILLIFLUIDIC MODEL OF THE BBB/BRAIN AS PART OF THE MICROBIOTA-GUT-BRAIN AXIS MINERVA PLATFORM

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

Lucia Boeri[1], Simone Perottoni[1], Francesca Donnaloja[1], Federica Fusco[1], Diego Albani[2], Carmen Giordano[1]

Aims The human brain is a complex machinery whose pathological perturbation leads to several disorders, including Alzheimer's disease (AD). Engineering brain structure and neural networks is challenging, also because we need to simulate fluid movements inside the parenchyma. In the frame of the MINERVA project that wants to reproduce in vitro the microbiota-gut-brain axis [http://www.minerva.polimi.it/] we developed a novel "brain-on-a-chip" using a fluidic model featuring the blood brain barrier (BBB) and main neural cell types. **Methods** We developed a millifluidic, optically accessible "on-a-chip" device that can host 2D or 3D hydrogel-embedded cells. To reproduce the BBB we cultured at opposite sides of a Transwell membrane human induced pluripotent stem cells (IPSCs) differentiated to astrocytes or endothelial cells. We tested the barrier integrity by analyzing transepithelial electric resistance (TEER) and FITC-dextrane permeability. IPSCs-derived neurons, microglia and astrocytes were also used to recapitulate brain parenchyma in a second on-a-chip device. **Results** Our millifluidic models of BBB and neural cells had comparable viability respect to static condition. The BBB device featured barrier properties and the whole system confirmed its suitability for the MINERVA aims. **Conclusions** IPSCs are a promising in vitro tool for disease modeling. Our millifluidic model can host iPSCs maintaining cell viability and BBB integrity. IPSCs derived from AD patients or genetically modified could be easily integrated to create a fluidic AD pathological model. **Acknowledgement** MINERVA project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement N° 724734).

Using integrated meta-omics to appreciate the role of the gut microbiota in epilepsy.
The way the human microbiota may modulate neurological pathologies is a fascinating matter of research. Epilepsy is a common neurological disorder, which has been largely investigated in correlation with microbiota health and function. However, the mechanisms that regulate this apparent connection are scarcely defined, and extensive effort has been conducted to understand the role of microbiota in preventing and reducing epileptic seizures. Intestinal bacteria seem to modulate the seizure frequency mainly by releasing neurotransmitters and inflammatory mediators. In order to elucidate the complex microbial contribution to epilepsy pathophysiology, integrated meta-omics could be pivotal. In fact, the combination of two or more meta-omics approaches allows a multifactorial study of microbial activity within the frame of disease or drug treatments. In this review, we provide information depicting and supporting the use of multi-omics to study the microbiota-epilepsy connection. We described different meta-omics analyses (metagenomics, metatranscriptomics, metaproteomics and metabolomics), focusing on current technical challenges in stool collection procedures, sample extraction methods and data processing. We further discussed the current advantages and limitations of using the integrative approach of multi-omics in epilepsy investigations.

Technological tools and strategies for culturing human gut microbiota in engineered in vitro models.
The gut microbiota directly impacts the pathophysiology of different human body districts. Consequently, microbiota investigation is an hot topic of research and its in vitro culture has gained extreme interest in different fields. However, the high sensitivity of microbiota to external stimuli, such as sampling procedure, and the physicochemical complexity of the gut environment make its in vitro culture a challenging task. New engineered microfluidic gut-on-a-chip devices have the potential to model some important features of the intestinal structure, but they are usually unable to sustain culture of microbiota over an extended period of time. The integration of gut-on-a-chip devices with bioreactors for continuous bacterial culture would lead to fast advances in the study of microbiota-host crosstalk. In this review, we summarize the main technologies for the

continuous culture of microbiota as upstream systems to be coupled with microfluidic devices to study bacteria-host cells communication. The engineering of integrated microfluidic platforms, capable of sustaining both anaerobic and aerobic cultures, would be the starting point to unveil complex biological phenomena proper of the microbiota-host crosstalks, paving to way to multiple research and technological applications.

Microbiota-Host Immunity Communication in Neurodegenerative Disorders: Bioengineering Challenges for In Vitro Modeling.
Human microbiota communicates with its host by secreting signaling metabolites, enzymes, or structural components. Its homeostasis strongly influences the modulation of human tissue barriers and immune system. Dysbiosis-induced peripheral immunity response can propagate bacterial and pro-inflammatory signals to the whole body, including the brain. This immune-mediated communication may contribute to several neurodegenerative disorders, as Alzheimer's disease. In fact, neurodegeneration is associated with dysbiosis and neuroinflammation. The interplay between the microbial communities and the brain is complex and bidirectional, and a great deal of interest is emerging to define the exact mechanisms. This review focuses on microbiota-immunity-central nervous system (CNS) communication and shows how gut and oral microbiota populations trigger immune cells, propagating inflammation from the periphery to the cerebral parenchyma, thus contributing to the onset and progression of neurodegeneration. Moreover, an overview of the technological challenges with in vitro modeling of the microbiota-immunity-CNS axis, offering interesting technological hints about the most advanced solutions and current technologies is provided.

The nuclear import of the transcription factor MyoD is reduced in mesenchymal stem cells grown in a 3D micro-engineered niche.
Smart biomaterials are increasingly being used to control stem cell fate in vitro by the recapitulation of the native niche microenvironment. By integrating experimental measurements with numerical models, we show that in mesenchymal stem cells grown inside a 3D synthetic niche both nuclear transport of a myogenic factor and the passive nuclear diffusion of a smaller inert protein are reduced. Our results also suggest that cell morphology modulates nuclear proteins import through a partition of the nuclear envelope surface, which is a thin but extremely permeable annular portion in cells cultured on 2D substrates. Therefore, our results support the hypothesis that in stem cell differentiation, the nuclear import of gene-regulating transcription factors is controlled by a strain-dependent nuclear envelope permeability, probably related to the reorganization of stretch-activated nuclear pore complexes.

Increased transcription of transglutaminase 1 mediates neuronal death in in vitro models of neuronal stress and Aβ1-42-mediated toxicity.
Alzheimer's disease (AD) is the most common cause of dementia. At the pre-symptomatic phase of the disease, the processing of the amyloid precursor protein (APP) produces toxic peptides, called amyloid-β 1-42 (Aβ 1-42). The downstream effects of Aβ 1-42 production are not completely uncovered. Here, we report the involvement of transglutaminase 1 (TG1) in in vitro AD models of neuronal toxicity. TG1 was increased at late stages of the disease in the hippocampus of a mouse model of AD and in primary cortical neurons undergoing stress. Silencing of TGM1 gene was sufficient to prevent Aβ-mediated neuronal death. Conversely, its overexpression enhanced cell death. TGM1 upregulation was mediated at the transcriptional level by an activator protein 1 (AP1) binding site that when mutated halted TGM1 promoter activation. These results indicate that TG1 acts downstream of Aβ-toxicity, and that its stress-dependent increase makes it suitable for pharmacological intervention.

Advantages and limitations of a supernegative GFP in facilitating MyoD intracellular tracking.
Despite intracellular molecular dynamics being fundamental to understand pathological, biomechanical or biochemical events, several processes are still not clear because of the difficulty of monitoring and measuring these phenomena. To engineer an effective fluorescent tool useful to improve protein intracellular tracking studies, we fused a supernegative green fluorescent protein, (-30)GFP, to a myogenic transcription factor, MyoD. The (-30)GFP-MyoD was able to pass the plasma membrane when complexed with cationic lipids. Fluorescence confocal microscopy showed the protein delivery in just 3 hours with high levels of protein transduction efficiency. Confocal acquisitions also confirmed the maintenance of the MyoD nuclear localization. To examine how the supernegative GFP influenced MyoD activity, we did gene expression analyses, which showed an inhibitory effect of (-30)GFP on transcription factor function. This negative effect was possibly due to a

charge-driven interference mechanism, as suggested by further investigations by molecular dynamics simulations. Summarizing these results, despite the functional limitations related to the charge structural characteristics that specifically affected MyoD function, we found (-30)GFP is a suitable fluorescent label for improving protein intracellular tracking studies, such as nucleocytoplasmic transport in mechanotransduction.

Mechanical regulation of nucleocytoplasmic translocation in mesenchymal stem cells: characterization and methods for investigation.
Mesenchymal stem cells (MSCs) have immune-modulatory and tissue-regenerative properties that make them a suitable and promising tool for cell-based therapy application. Since the bio-chemo-mechanical environment influences MSC fate and behavior, the understanding of the mechanosensors involved in the transduction of mechanical inputs into chemical signals could be pivotal. In this context, the nuclear pore complex is a molecular machinery that is believed to have a key role in force transmission and in nucleocytoplasmic shuttling regulation. To fully understand the nuclear pore complex role and the nucleocytoplasmic transport dynamics, recent advancements in fluorescence microscopy provided the possibility to study passive and facilitated nuclear transports also in mechanically stimulated cell culture conditions. Here, we review the current available methods for the investigation of nucleocytoplasmic shuttling, including photo-perturbation-based approaches, fluorescence correlation spectroscopy, and single-particle tracking techniques. For each method, we analyze the advantages, disadvantages, and technical limitations. Finally, we summarize the recent knowledge on mechanical regulation of nucleocytoplasmic translocation in MSC, the relevant progresses made so far, and the future perspectives in the field.

Advanced Organ-on-a-Chip Devices to Investigate Liver Multi-Organ Communication: Focus on Gut, Microbiota and Brain.
The liver is a key organ that can communicate with many other districts of the human body. In the last few decades, much interest has focused on the interaction between the liver and the gut microbiota, with their reciprocal influence on biosynthesis pathways and the integrity the intestinal epithelial barrier. Dysbiosis or liver disorders lead to0 epithelial barrier dysfunction, altering membrane permeability to toxins. Clinical and experimental evidence shows that the permeability hence the delivery of neurotoxins such as LPS, ammonia and salsolinol contribute to neurological disorders. These findings suggested multi-organ communication between the gut microbiota, the liver and the brain. With a view to in vitro modeling this liver-based multi-organ communication, we describe the latest advanced liver-on-a-chip devices and discuss the need for new organ-on-a-chip platforms for in vitro modeling the in vivo multi-organ connection pathways in physiological and pathological situations.

Influence of the static magnetic field on cell response in a miniaturized optically accessible bioreactor for 3D cell culture.
Hydraulic sealing is a crucial condition for the maintenance of sterility during long term operation of microfluidic bioreactors. We developed a miniaturized optically accessible bioreactor (MOAB) allowing perfused culture of 3D cellularised constructs. In the MOAB, the culture chambers are sealed by magnets that generate a weak static magnetic field (SMF). Here, we predicted computationally the exact level of SMF to which cells are subjected during culture in the MOAB and we assessed its influence on the viability, metabolic activity and gene expression of neuroblastoma-derived cells cultured up to seven days. The predicted SMF ranged from 0.32 to 0.57 T using an axial-symmetric model of a single chamber, whereas it ranged from 0.35 to 0.62 T using a 3D model of the complete device. Cell function was evaluated in SH-SY5Y neuroblastoma cells at 2 and 7 days of culture in the MOAB, compared to 2D monolayer, 3D non-perfused constructs, and 3D perfused constructs cultured in a modified MOAB with magnet-free sealing. We measured the cell metabolic activity normalized by the DNA content and the expression levels of heat-shock protein 70 (Hsp-70), Bcl-2 and Bax. We found that the level of SMF applied to cells in the MOAB did not influence their metabolic activity and exerted a stressful effect in 2D monolayer, not confirmed in 3D conditions, neither static not perfused. Instead, the magnets provided a significantly greater hydraulic sealing in long-term culture, thus the MOAB might be potentially exploitable for the development of reliable in vitro models of neurodegeneration.

Exome sequencing in an Italian family with Alzheimer's disease points to a role for seizure-related gene 6 (SEZ6) rare variant R615H.
The typical familial form of Alzheimer's disease (FAD) accounts for about 5% of total Alzheimer's disease (AD) cases. Presenilins (PSEN1 and PSEN2) and amyloid-β (A4) precursor protein (APP) genes carry all reported FAD-linked mutations. However, other genetic loci may be involved in AD. For instance, seizure-related gene 6 (SEZ6) has been reported in brain

development and psychiatric disorders and is differentially expressed in the cerebrospinal fluid of AD cases. Alzheimers Res Ther, 2018; 10

INVOLVEMENT OF MENINGEAL SENSORY NERVES IN THE PATHOMECHANISM OF SUBARACHNOID HEMORRHAGE

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

Adham Algerafi, Thannoon Masood, Gyöngyi Kis, Szandra Lakatos, Mária Dux, Judit Rosta
University of Szeged, Department Of Physiology, Albert Szent-györgyi Medical School, Szeged, Hungary

Background Intracranial sensory nerves, mainly arise from trigeminal ganglion (TG) have a functional role on cerebrovascular tone due to the release of the vasodilator mediator calcitonin-gene related peptide (CGRP). An imbalance of vasoactive mechanisms may result in prolonged spasm. Cerebral vasospasm is a serious consequence of s*ubarachnoid hemorrhage* (SAH)- the bleeding between brain covering layers, the meninges. Diminished CGRP-content in cerebral nerves following SAH had been described. Our study aims to investigate the involvement of CGRP-containing meningeal afferents in the pathomechanism of SAH. *Methods* SAH was evoked by intracisternal injection of autologous blood in rats. 72 hours after the injection, the outermost meningeal layer, dura mater encephali and TG were removed. The density of CGRP-containing nerves was determined by immunohistochemical analysis in dural preparations. Retrograde tracer was used to identify trigeminal region innervating the dura and CGRP-immunopositive cells were counted. ATF3, as an injury marker was used to determine the damage of neurons. Furthermore, expression level of CGRP in TG was measured by RT-PCR 72 hours following SAH. *Results* Our results showed a decreased density of CGRP-positive meningeal afferents following SAH. However, the number of CGRP-immunopositive trigeminal neurons was retained with moderately increased expression of CGRP in TG. The number of ATF3-immunopositive neurons was not increased comparing to control. *Conclusion* Decreased CGRP-content of meningeal afferents supports that vasoactive sensory functions diminish after SAH. However, retained CGRP synthesis shows that not damage of primary sensory neurons is the reason of decreased amount of CGRP in sensory nerves intracranially.

HETEROGENEITY AND DEVELOPMENTAL DYNAMICS OF LYVE-1 PERIVASCULAR MACROPHAGES DISTRIBUTION IN THE MOUSE BRAIN

POSTER SESSION 06 - SECTION: CEREBROVASCULAR PHYSIOLOGY

Marie Karam[1], Isabelle Brunet[2]
[1]CIRB, collège de France, Molecular Control Of The Neurovascular Development Research Group, Paris, France, [2]CIRB, Collège de France, Molecular Control Of The Neurovascular Development Research Group, Paris, France

Brain perivascular macrophages (PVMs) are border-associated macrophages situated along blood vessels in the Virchow-Robin space and are thus found at a unique anatomical position between the endothelium and the parenchyma. Owing to their location and phagocytic capabilities, PVMs are regarded as important components that regulate various aspects of brain physiology in health and pathophysiological states. Here, we used LYVE-1 to identify PVMs in the mouse brain using used brain-tissue sections and cleared whole-brains to learn about how they are distributed within the brain and across different developmental postnatal stages. We find that LYVE-1$^+$PVMs associate with the vasculature in different patterns and proportions depending on vessel diameter or arterio-venous differentiation. LYVE-1$^+$PVMs relate to blood vessels in a brain-region-dependent manner. We show that their postnatal distribution is developmentally dynamic and peaks at P10-P20 depending on the brain region. PVMs express CD206 (another non-lymphatic marker of PVMs) and LYVE-1 at different ratio throughout the brain suggesting that PVMs possess a unique molecular signature. We further demonstrate that their density is reduced in the APP/PS1 mouse model of Alzheimer's Disease inversely proportional to beta-amyloid deposits. Interestingly, we found that PVMs conserve CD206 but not LYVE-1 expression in APP/PS1 compared to WT, thus losing their lymphatic and possibly drainage abilities. In conclusion, our results reveal unexpected heterogeneity and dynamics of LYVE-1$^+$PVMs, with selective coverage in brain vasculature, compatible with potential unexplored roles for this population of PVMs in postnatal development, and in regulating brain functions in steady-state and disease conditions.

T-TYPE CALCIUM CURRENT IN PKCγ NEURONS GATING CHRONIC PAIN IN THE DORSAL SPINAL CORD IN MICE

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Célia Cuculière[1], Vanessa Soubeyre[1], Jean Chemin[1], Emmanuel Deval[2], Eric Lingueglia[2], Emmanuel Bourinet[1], Pierre-François Mery[1]

Pain management with current analgesic drugs is often a failure: 20% of the population suffers from chronic pain. In the quest for alternative targets, our team has shown that low-threshold calcium channels (T-type channels), and in particular the Cav3.2 isoform, are targets of interest in the search for new pain medications (Candelas et al. 2019; François et al. 2015). The roles of these channels, in the somatosensory system may be involved in the development and maintenance of chronic pain. Genetic ablation of Cav3.2 in the dorsal horn of the spinal cord is sufficient to induce an anti-allodynic effect in mice. This putative therapeutic target, Cav3.2, is homogeneously expressed in excitatory interneurons expressing protein kinase C-γ (PKCγ) in the spinal dorsal horn. These PKCγ neurons play a key role in neuropathic pain, during which they transmit non-nociceptive excitation to nociceptive projection neurons. By combining electrophysiology, immunohistology, and clarification techniques, we were able to examine the effect of pharmacological and/or genetic inhibition of T-type channels selectively in PKCγ neurons or in the entire spinal network. Our results suggest multiple roles for Cav3.2 in PKCγ-expressing neurons. In a mouse model of neuropathic pain (spared nerve injury: SNI), we found time-dependent remodelling of synaptic currents in PKCγ neurons and genetic inactivation of Cav3.2 in PKCγ-expressing neurons does not always oppose its effect to that of SNI. Follow-up experiments will illustrate the role of other T-type channel isoforms (Cav3.1 and Cav3.3), using a viral/sh-RNA strategy targeted to PKCγ expressing neurons in sham and SNI mice.

Cav3.2 T-type calcium channels are present throughout nociceptive pathways, from free endings of primary afferent neurons up to structures of the pain matrix. Previous studies focalized on primary afferent, have shown its important pronociceptive role in acute and pathological rodent pain models. At the first pit stop of somatosensory information processing in the dorsal horn of the spinal cord, Cav3.2 is abundant however; its role remains to be resolved. Thanks to local viral delivery of Cre recombinase in spinal cord of Cav3.2$^{GFP\text{-}flox}$ KI mice; we achieved a robust local Cav3.2 dorsal horn-specific KO. This spinal KO prophylactically and to a lesser extent curatively alleviates all the cardinal signs of neuropathic pain. Nonetheless, in a clinical perspective, we believe it is imperative to extend this approach to study human spinal cord biology. This will guide the priority and relevance of our future studies in mouse and serve as a foundation for understanding molecular changes that accompany human chronic pain. In that respect we developed, a unique research axis with the Montpellier hospital on human spinal and dorsal roots tissues collected from human donors during organ transplant procedures. The presentation will highlight these approaches including recent molecular and functional data obtained from human tissues.

THE HETEROGENEITY OF SYNAPTIC NMDA RECEPTOR RESPONSES WITHIN INDIVIDUAL LAMINA I PAIN PROCESSING NEURONS IS CONSERVED ACROSS SEX AND SPECIES

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Annemarie Dedek[1,2], Emine Topcu[1], Christopher Dedek[1], Eve Tsai[2,3,4], Michael Hildebrand[1,2]
[1]Carleton University, Department Of Neuroscience, Ottawa, Canada, [2]The Ottawa Hospital Research Institute, Neurosciences Department, Ottawa, Canada, [3]The Ottawa Hospital, Department Of Surgery, Ottawa, Canada, [4]University of Ottawa, Brain And Mind Research Institute, Ottawa, Canada

Excitatory glutamatergic NMDA receptors (NMDARs) are key regulators of spinal pain processing, and yet the biophysical properties of NMDARs in dorsal horn nociceptive neurons remain poorly understood. Despite the clear clinical importance, it is unknown whether the molecular and functional properties of NMDAR synaptic responses are conserved between males and females as well as from rodents to humans. To address these translational gaps, we systematically compared individual and averaged excitatory synaptic responses from lamina I pain processing neurons of adult Sprague Dawley rats and human organ donors, including both sexes. By combining patch-clamp recordings of outward miniature excitatory postsynaptic currents with non-biased data analysis approaches, we uncovered a wide range in decay constants of excitatory synaptic events within individual lamina I neurons. Decay constants of quantal synaptic responses were distributed in a continuum from 1-20 ms to greater than 1000 ms, suggesting that individual lamina I neurons may contain AMPA receptor (AMPAR)-only as well as GluN2A-, GluN2B-, and GluN2D-dominated synaptic events. This intraneuronal heterogeneity in AMPA receptor- and NMDAR-mediated decay kinetics was conserved across both sex and species. The amplitude of synaptic responses was also conserved between event types and across sex for both rats and humans. The vast heterogeneity in decay rates of excitatory synaptic events within individual lamina I pain processing neurons may enable synapse-specific forms of plasticity and sensory integration within dorsal horn nociceptive networks.

The T-type calcium channel antagonist, Z944, reduces spinal excitability and pain hypersensitivity.
T-type voltage-gated calcium channels are an emerging therapeutic target for neurological disorders including epilepsy and pain. Inhibition of T-type channels reduces the excitability of peripheral nociceptive sensory neurons and reverses pain hypersensitivity in male rodent pain models. However, administration of peripherally restricted T-type antagonists failed to show efficacy in multiple clinical and preclinical pain trials, suggesting that inhibition of peripheral T-type channels alone may be insufficient for pain relief.

Loss of STEP61 couples disinhibition to N-methyl-d-aspartate receptor potentiation in rodent and human spinal pain processing.
Dysregulated excitability within the spinal dorsal horn is a critical mediator of chronic pain. In the rodent nerve injury model of neuropathic pain, BDNF-mediated loss of inhibition (disinhibition) gates the potentiation of excitatory GluN2B N-methyl-d-aspartate receptor (NMDAR) responses at lamina I dorsal horn synapses. However, the centrality of this mechanism across pain states and species, as well as the molecular linker involved, remain unknown. Here, we show that KCC2-dependent disinhibition is coupled to increased GluN2B-mediated synaptic NMDAR responses in a rodent model of inflammatory pain, with an associated downregulation of the tyrosine phosphatase STEP61. The decreased activity of STEP61 is both necessary and sufficient to prime subsequent phosphorylation and potentiation of GluN2B NMDAR by BDNF at lamina I synapses. Blocking disinhibition reversed the downregulation of STEP61 as well as inflammation-mediated behavioural hypersensitivity. For the first time, we characterize GluN2B-mediated NMDAR responses at human lamina I synapses and show that a human ex vivo BDNF model of pathological pain processing downregulates KCC2 and STEP61 and upregulates phosphorylated GluN2B at dorsal horn synapses. Our results demonstrate that STEP61 is the molecular brake that is lost following KCC2-dependent disinhibition and that the decrease in STEP61 activity drives the potentiation of excitatory GluN2B NMDAR responses in rodent and human models of pathological pain. The ex vivo human BDNF model may thus form a

translational bridge between rodents and humans for identification and validation of novel molecular pain targets.

Potentiation of Synaptic GluN2B NMDAR Currents by Fyn Kinase Is Gated through BDNF-Mediated Disinhibition in Spinal Pain Processing.
In chronic pain states, the neurotrophin brain-derived neurotrophic factor (BDNF) transforms the output of lamina I spinal neurons by decreasing synaptic inhibition. Pain hypersensitivity also depends on N-methyl-D-aspartate receptors (NMDARs) and Src-family kinases, but the locus of NMDAR dysregulation remains unknown. Here, we show that NMDAR-mediated currents at lamina I synapses are potentiated in a peripheral nerve injury model of neuropathic pain. We find that BDNF mediates NMDAR potentiation through activation of TrkB and phosphorylation of the GluN2B subunit by the Src-family kinase Fyn. Surprisingly, we find that Cl-dependent disinhibition is necessary and sufficient to prime potentiation of synaptic NMDARs by BDNF. Thus, we propose that spinal pain amplification is mediated by a feedforward mechanism whereby loss of inhibition gates the increase in synaptic excitation within individual lamina I neurons. Given that neither disinhibition alone nor BDNF-TrkB signaling is sufficient to potentiate NMDARs, we have discovered a form of molecular coincidence detection in lamina I neurons.

INFLAMMATION TRIGGERS HOMEOSTATIC PROCESSES IN THE TRIGEMINAL PAIN PATHWAY

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Ben Title, Shaya Lev, Ben Katz, Yosef Yarom, Alexander Binshtok
Hebrew University of Jerusalem, Medical Neurobiology, Jerusalem, Israel

Trigeminal pain pathway involves the detection of noxious stimulus by trigeminal ganglion (TG) nociceptors, which innervate orofacial areas and terminate in the trigeminal nucleus caudalis (TNc). TNc projection neurons (PNs) integrate nociceptive input from the periphery with local interneurons activity, and transmit the information to higher brain regions. Although the anatomy of the trigeminal pathway is well characterized, its physiological function is less understood. Here we ask how nociceptive input is encoded by TNc PNs, and how inflammation affects their properties and function and hence their output. We generated a mouse model, which enables the identification of TNc PNs as well as activation of TG nociceptors using optogenetics. Behaviorally, we show that optogenetic activation of TG nociceptive fibers evokes nocifensive response. Physiologically, we demonstrate that TNc PNs differ in their responses to optogenetic stimulation of the nociceptive axons, with two prominent responses: (1) excitation and (2) excitation followed by inhibition. We further characterized TNc PNs during inflammation using UV-keratitis model which results with corneal inflammation. TNc PNs in the inflammatory condition displayed similar distribution of responses to activation of the nociceptive axons. Surprisingly, in these conditions, PNs displayed reduced excitability, as manifested by a reduction in their input resistance and reduced firing response to current injections. Corneal inflammation in the UV-keratitis model is known to result with increased excitability of TG nociceptive fibers, implying increased activation of TNc PNs. We suggest that TNc PNs reduce their excitability as a regulatory mechanism to reduce their activity and maintain homeostasis during inflammation.

Pogz deficiency leads to transcription dysregulation and impaired cerebellar activity underlying autism-like behavior in mice. Several genes implicated in autism spectrum disorder (ASD) are chromatin regulators, including POGZ. The cellular and molecular mechanisms leading to ASD impaired social and cognitive behavior are unclear. Animal models are crucial for studying the effects of mutations on brain function and behavior as well as unveiling the underlying mechanisms. Here, we generate a brain specific conditional knockout mouse model deficient for Pogz, an ASD risk gene. We demonstrate that Pogz deficient mice show microcephaly, growth impairment, increased sociability, learning and motor deficits, mimicking several of the human symptoms. At the molecular level, luciferase reporter assay indicates that POGZ is a negative regulator of transcription. In accordance, in Pogz deficient mice we find a significant upregulation of gene expression, most notably in the cerebellum. Gene set enrichment analysis revealed that the transcriptional changes encompass genes and pathways disrupted in ASD, including neurogenesis and synaptic processes, underlying the observed behavioral phenotype in mice. Physiologically, Pogz deficiency is associated with a reduction in the firing frequency of simple and complex spikes and an increase in amplitude of the inhibitory synaptic input in cerebellar Purkinje cells. Our findings support a mechanism linking heterochromatin dysregulation to cerebellar circuit dysfunction and behavioral abnormalities in ASD.

Corticotropin-releasing factor increases Purkinje neuron excitability by modulating sodium, potassium, and Ih currents. Corticotropin-releasing factor (CRF) is a neuromodulator closely associated with stress responses. It is synthesized and released in the central nervous system by various neurons, including neurons of the inferior olive. The targets of inferior olivary neurons, the cerebellar Purkinje neurons (PNs), are endowed with CRF receptors. CRF increases the excitability of PNs in vivo, but the biophysical mechanism is not clear. Here we examine the effect of CRF on the firing properties of PNs using acute rat cerebellar slices. CRF increased the PN firing rate, regardless of whether they were firing tonically or switching between firing and quiescent periods. Current- and voltage-clamp experiments showed that the increase in firing rate was associated with a voltage shift of the activation curve of the persistent sodium current and hyperpolarizing-activated current, as well as activation of voltage-dependent potassium current. The multiple effects on various ionic currents, which

are in agreement with the possibility that activation of CRF receptors triggers several intracellular pathways, are manifested as an increase excitability of PN.

Platelet-derived growth factor activates nociceptive neurons by inhibiting M-current and contributes to inflammatory pain.
Endogenous inflammatory mediators contribute to the pathogenesis of pain by acting on nociceptors, specialized sensory neurons that detect noxious stimuli. Here, we describe a new factor mediating inflammatory pain. We show that platelet-derived growth factor (PDGF)-BB applied in vitro causes repetitive firing of dissociated nociceptor-like rat dorsal root ganglion neurons and decreased their threshold for action potential generation. Injection of PDGF-BB into the paw produced nocifensive behavior in rats and led to thermal and mechanical pain hypersensitivity. We further detailed the biophysical mechanisms of these PDGF-BB effects and show that PDGF receptor-induced inhibition of nociceptive M-current underlies PDGF-BB-mediated nociceptive hyperexcitability. Moreover, in vivo sequestration of PDGF or inhibition of the PDGF receptor attenuates acute formalin-induced inflammatory pain. Our discovery of a new pain-facilitating proinflammatory mediator, which by inhibiting M-current activates nociceptive neurons and thus contributes to inflammatory pain, improves our understanding of inflammatory pain pathophysiology and may have important clinical implications for pain treatment.

CIRCADIAN REGULATION OF TRIGEMINAL PAIN CIRCUITS

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Florian Zirpel, Liting Wei, Zameel Cader
University of Oxford, Nuffield Department Of Clinical Neurosciences, Oxford, United Kingdom

Circadian characteristics of pain have been described in humans and animal models, but the underlying mechanisms remain unclear. Preliminary data from our group suggest that trigeminal nociceptor activity and orofacial pain behaviour vary depending on the time of day. Patch clamp recordings from acute trigeminal nucleus caudalis (TNC) slices revealed differences in excitatory drive between two time points assessed, with increased spontaneous input to layer I TNC neurons at the time point corresponding to decreased pain behaviour. At this time point, activation of primary nociceptors using the TRPV1 agonist capsaicin did not affect the frequency of sEPSCs in presence of the $GABA_A$ blocker picrotoxin. Surprisingly, in absence of synaptic blockers, a third of neurons at this time point showed reduced sEPSC rates when capsaicin was applied. Furthermore, sIPSC rate was modulated by capsaicin depending on the time of day. Global knockout of the clock genes *Cry1* and *Cry2*, and sensory neuron-specific ablation of *Bmal1* abolished the variation of synaptic currents between time points. Collectively, the data supports the role of circadian mechanisms in intraspinal modulation of trigeminal nociceptive traffic.

The trigeminal ganglion (TG) contains clusters of cell bodies of *highly specialized sensory neurons* innervating the ophthalmic, maxillary and the mandibular orofacial regions. The functional imaging within the TG is highly challenging due to anatomical features: small size and deep localization. Aims: This study aimed at imaging of both TG blood vasculature at microscopic resolution and hemodynamic responses evoked by orofacial stimulations in anesthetized rats using functional ultrasound imaging (fUSI). Methods: fUSI of TG was done in anesthetized rats. Peripheral stimulations included mechanical (soft brush) and chemical (capsaisin) corneal stimulations and mechanical stimulations of the ophthalmic and maxillary territories using von Frey filaments. Results: Despite the small number of sensory neurons within the TG, fUSI was able to quantify highly localized hemodynamic response in the ipsilateral TG, constituting the first demonstration of functional somatotopy**.** The *in vivo* quantitative imaging of the TG's vasculature using Ultrafast Localisation Microscopy revealed particular features of the vascularization (strong density and high speed of blood flow) of the area containing the sensory neurons, that are likely the origin of this strong vaso-trigeminal response. Conclusions: This innovative imaging approach opens the path for future studies on the mechanisms underlying changes in trigeminal local blood flow and evoked hemodynamic responses, key mechanisms and readouts for the understanding and treatment of debilitating trigeminal pain conditions.

Rhythmic activity is essential for nervous system function. The ability of individual neurons to integrate and encode information from inputs in defined frequency bands depends on their intrinsic resonant properties. The aims of this work were to examine the subthreshold resonance in superficial dorsal horn neurons (sDHN) and its relation to hyperpolarization activated currents (Ih). Whole-cell recordings were obtained from sDHN using in vitro horizontal spinal cord slices from adult mice. Sinusoidal current injection was applied to analyze resonance behavior. Voltage-clamp recordings were obtained from the same neurons to study the presence of Ih and their characteristics. Computer-modelled Ih was injected in real neurons using dynamic-clamp to further assess the influence of this current in resonance. Fifteen percent of the recorded neurons presented a clear resonance peak at a frequency between 1-3 Hz, most of these neurons showed Ih. In each individual neuron, the magnitude of the resonance peak was related to the density of Ih. H currents with different kinetic properties were recorded in sDHN, and therefore slow and fast Ih currents were modelled. In dynamic clamp experiments, injection of both types of currents reproduced the resonance behavior observed in neurons that expressed real Ih. Our results demonstrate that the presence of Ih produced neuronal resonance in sDHN. This behavior may be implicated in somatosensory processing at the spinal cord level, and the modulation of these currents may serve as a regulatory mechanism for neuronal integration. Financial support was obtained from the University of Alcala, grant no. PIUAH21/CCS-039

DUAL PI3Kδ/γ INHIBITOR DUVELISIB PREVENTS DEVELOPMENT OF CHEMOTHERAPY INDUCED NEUROPATHIC PAIN

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Pavel Adamek, Mario Heles, Anirban Bhattacharyya, Monica Pontearso, Jakub Slepicka, Jiri Palecek
Czech Academy of Sciences, Institute Of Physiology, Praha, Czech Republic

The development of painful paclitaxel-induced peripheral neuropathy (PIPN) represents a major dose-limiting side effect of paclitaxel chemotherapy. Our experiments show a promising effect of duvelisib (Copiktra™), a novel FDA approved PI3Kδ/γ isoform-specific inhibitor, in preventing increased mechanical sensitivity and pronociceptive signalling in dorsal root ganglia (DRG) and spinal cord dorsal horn (SCDH) in rat and mouse model of PIPN. Duvelisib blocked the development of mechanical hyperalgesia in both males and females. Duvelisib also prevented paclitaxel-induced sensitization of TRPV1 receptors, increased PI3K/Akt-signalling in small-diameter DRG neurons and an increase of $CD68^{+}$ cells within DRGs. Specific optogenetic stimulation of inhibitory neurons combined with patch-clamp recording revealed that duvelisib prevented paclitaxel-induced reduction of inhibitory currents in SCDH excitatory neurons. Enhanced excitatory and reduced inhibitory neurotransmission in the SCDH following PIPN was also alleviated by duvelisib application. In summary, duvelisib showed a promising ability to prevent neuropathic pain in PIPN. The potential use of our findings in human medicine may be augmented by the fact that duvelisib is an FDA approved drug with known side effects. This work was supported by the Grant Agency of the Czech Republic GACR 20-19136S.

TAFA4 RELIEVES INJURY-INDUCED MECHANICAL ALLODYNIA THROUGH LRP1 AND MODULATION OF SPINAL A-TYPE POTASSIUM CURRENTS

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Catarina Santos, Sungjae Yoo, Nadine Clerc, Aziz Moqrich, Francis Castets
AIX MARSEILLE UNIVERSITE, Ibdm-cnrs Umr7288, Marseille cedex, France

Pain, whether acute or persistent, is a serious medical problem worldwide. However, its management remains unsatisfactory, and new analgesic molecules are therefore required. We show here that TAFA4 reverses inflammatory, postoperative and spared nerve injury (SNI)-induced mechanical hypersensitivity in male and female mice. TAFA4-mediated analgesia requires functional LRP1, as LRP1 inhibition *in vivo* abolished its analgesic effect. SNI induces a selective decrease in I_A in outer lamina II excitatory interneurons (L-IIo-ExIN), accompanied by a concomitant increase in I_A and decrease in I_h in inner lamina II inhibitory interneurons (L-IIi-InhIN). Remarkably, TAFA4 rescued these SNI-induced current alterations in an LRP1-dependent manner in both interneuron subtypes. Finally, SNI decreased the density of TAFA4$^+$ terminals in the spinal region, as shown by high levels of microglial activation. Our findings provide mechanistic insight into the mechanism by which TAFA4 reverses injury-induced mechanical hypersensitivity, by restoring normal spinal neuron activity, and highlight the considerable potential of TAFA4 as a treatment for pain.

SEX DIFFERENCES IN CHLORIDE HOMEOSTASIS OF C-FIBER PRIMARY AFFERENTS IN THE SPINAL CORD DORSAL HORN.

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Reza Hazrati[1], Feng Wang[2], Iason Keramidis[1], Antoine Godin[1], Yves De Koninck[1]
[1]Université Laval, Faculty Of Medicine, Québec, Canada, [2]CERVO Brain Research Centre, Department Of Psychiatry And Neuroscience, Quebec City, Canada

Introduction: Intracellular Cl^- concentration ($[Cl^-]i$) is high in primary sensory neurons due to the activity of the Na^+-K^+-Cl^- cotransporter 1 (NKCC1), causing greater Cl^- accumulation than typically seen in CNS neurons. Consequently, central terminals of primary afferents in the spinal dorsal horn experience depolarization upon activation of $GABA_A$ receptors ($GABA_AR$). Thus, regulation of $[Cl^-]_i$ in these terminals may significantly affect transmitter release. Determining the exact $[Cl^-]_i$ in C-fiber terminals is pivotal to understand sensory processing. Methods: To image $[Cl^-]_i$ we used the genetically-encoded ratiometric Cl^- sensor, superclomeleon, which was virally transduced selectively in C-fibers in NaV1.8-cre male and female mice. We did 2-photon microscopy in acute spinal cord slices and on the acutely delaminated spinal cord in anesthetized mice. The $GABA_AR$ agonist and antagonist muscimol and bicuculline, as well as the NKCC1 antagonist bumetanide, were used to modulate $[Cl^-]_i$ in afferent terminals in the dorsal horn. NKCC1 protein and mRNA levels in the dorsal root ganglia were evaluated with western blot and RNAScope. Results: We found that $[Cl^-]_i$ in C-fibers was significantly higher in males than females. Bumetanide significantly decreased $[Cl^-]_i$ in males but not in females. Bicuculline increased significantly $[Cl^-]_i$ in females but not males C-fibers indicating a more important contribution of tonic $GABA_A$ signaling to $[Cl^-]_i$ in females. NKCC1 protein and mRNA were also significantly lower in females than males, consistent with the functional data. Conclusion: Presynaptic inhibition appears to be under distinct control by GABAergic inhibition between sexes, which should be taken into consideration in future studies.

Evaluation of different classes of histamine H and H receptor antagonist effects on neuropathic nociceptive behavior following tibial nerve transection in rats.
It seems that histamine release in the site of neuronal injury could contribute to the neuropathic pain mechanism. In the present study, we investigated the anti-allodynic effects of chronic administration of different classes of histamine H and H receptor antagonists on neuropathic nociceptive behavior following tibial nerve transection (TNT) in rats. Peripheral neuropathy was induced by TNT surgery. We performed acetone tests (AT) to record cold allodynia, Von Frey tests (VFT) to measure mechanical allodynia, double plate test (DPT) to evaluate thermal place preference/avoidance and open field test (OFT) for evaluation of animal activity. TNT rats showed a significant mechanical and cold allodynia compared to the sham group. Chlorpheniramine (5 and 15 mg/kg, i.p) significantly attenuated cold allodynia and prevented cold plate avoidance behavior and at the dose of 15 mg/kg remarkably decreased mechanical allodynia. Fexofenadine (10 and 30 mg/kg, p.o) significantly attenuated the mechanical allodynia and prevented cold plate avoidance. Ranitidine (5 and 15 mg/kg, i.p) significantly prevented cold plate avoidance behavior and at the dose of 15 mg/kg notably improved mechanical and cold allodynia. Famotidine (1 and 3 mg/kg, p.o) was ineffective on all nociceptive tests. Gabapantin (100 mg/kg, p.o) significantly improved all types of nociceptive behaviors. These results indicate that both blood brain barrier penetrating (chlorpheniramine) and poorly penetrating (fexofenadine) histamine H receptor antagonists could improve the neuropathic pain sign, but only the blood brain barrier penetrating histamine H receptor antagonist (ranitidine) could produce anti-allodynic effects in the TNT model of neuropathic pain in rats.

Effects of topical and systemic administration of Eugenia caryophyllata buds essential oil on corneal anesthesia and analgesia.
Clinical studies suggest that essential oil of Eugenia caryophyllata (Clove) buds (EOEC) is efficacious in the treatment of dental pain. In the present study, we investigated the analgesic and local anesthetic effects of EOEC and its possible

mechanisms of action in acute corneal pain in rats. EOEC was extracted by hydro-distillation in a Clevenger type apparatus from clove buds. The acute corneal pain was induced by applying a drop (40 µl) of 5 M NaCl solution on the corneal surface, and the numbers of eye wipes were counted during the first 30 s. The mechanical sensation of the cornea was evaluated by calibrated Von Frey filaments. Systemic administration of EOEC (100 and 200 mg/kg, SC) and morphine (2.5 and 5 mg/kg, IP) produced a significant antinociceptive effect in acute corneal pain. Pretreatment with naloxone or atropine prevented the EOEC-induced analgesia. However, L-arginine and methylene blue did not change the suppressive effect of EOEC on corneal pain response. Topical application of EOEC, eugenol and lidocaine significantly decreased corneal sensitivity. Combination treatments of eugenol (25 µg) with lidocaine (0.5%) and EOEC (50 µg) with lidocaine (0.5%) also significantly suppressed corneal sensitivity. Systemic administration of EOEC produced analgesia in the acute corneal pain through mechanisms that involved both opioidergic and cholinergic systems. In addition, topical instillation of EOEC, eugenol, and lidocaine produced local anesthesia in the rat cornea. Sub-anesthetic doses of EOEC or eugenol produced a significant local anesthetic effect when concurrently used with the sub-anesthetic dose of lidocaine.

ANALYSIS OF EFFECTIVE CONNECTIVITY BETWEEN DORSAL HORN NUERONS AND PRIMARY AFFERENTS FROM ADULT MICE

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Javier Lucas-Romero, Iván Rivera-Arconada, Jose Antonio Lopez-Garcia
University of Alcalá, Systems Biology, Alcalá de Henares, Spain

Aim. Excitability of central terminals from primary afferents is modulated by spinal interneurons located in the superficial dorsal horn. Our aim was to identify and characterise these neurons. **Methods**. We used horizontal slices of the lumbar spinal cord from adult mice maintained *in vitro*. Slices were 500 µm thick and kept superficial laminae and dorsal roots. Electrode matrixes were used to record spontaneous activity from 5-20 dorsal horn neurons simultaneously. Recordings from primary afferents were obtained with micro-suction electrodes from teased dorsal rootlets. Effective connectivity analysis was performed with an artificial intelligence tool built in house adapting the C5.0 algorithm. The Mathews Correlation Coefficient (MCC) was used as a single metric to estimate effective connectivity. **Results**. Successful recordings were obtained from 10 primary afferents and 50 dorsal horn neurons. High MCC values were obtained for 7 neurons which were considered putative presynaptic neurons. All of them exhibited irregular patterns of spontaneous activity. Five neurons produced characteristic short- high frequency bursts of activity at irregular intervals. In one case, two neurons with high MCC were related to the same afferent. In another experiment, one single neuron had high MCC values related to the 4 afferents recorded. For 2 afferents it was not possible to find neurons with relevant MCC values. **Conclusions**. In the superficial dorsal horn, putative presynaptic neurons to primary afferents have a characteristic pattern of spontaneous activity consisting of brisk bursts of activity at irregular intervals. Origin and classification of spontaneous discharges in mouse superficial dorsal horn neurons.
Superficial laminae of the spinal cord possess a considerable number of neurons with spontaneous activity as reported in vivo and in vitro preparations of several species. Such neurons may play a role in the development of the nociceptive system and/or in the spinal coding of somatosensory signals. We have used electrophysiological techniques in a horizontal spinal cord slice preparation from adult mice to investigate how this activity is generated and what are the main patterns of activity that can be found. The results show the existence of neurons that fire regularly and irregularly. Within each of these main types, it was possible to distinguish patterns of spontaneous activity formed by single action potentials and different types of bursts according to intra-burst firing frequency. Activity in neurons with irregular patterns was blocked by a mixture of antagonists of the main neurotransmitter receptors present in the cord. Approximately 82% of neurons with a regular firing pattern were insensitive to synaptic antagonists but their activity was inhibited by specific ion channel blockers. It is suggested that these neurons generate endogenous activity due to the functional expression of hyperpolarisation-activated and persistent sodium currents driving the activity of irregular neurons.

Discovering Effective Connectivity in Neural Circuits: Analysis Based on Machine Learning Methodology.
As multielectrode array technology increases in popularity, accessible analytical tools become necessary. Simultaneous recordings from multiple neurons may produce huge amounts of information. Traditional tools based on classical statistics are either insufficient to analyze multiple spike trains or sophisticated and expensive in computing terms. In this communication, we put to the test the idea that AI algorithms may be useful to gather information about the effective connectivity of neurons in local nuclei at a relatively low computing cost. To this end, we decided to explore the capacity of the algorithm C5.0 to retrieve information from a large series of spike trains obtained from a simulated neuronal circuit with a known structure. Combinatory, iterative and recursive processes using C5.0 were built to examine possibilities of increasing the performance of a direct application of the algorithm. Furthermore, we tested the applicability of these processes to a reduced dataset obtained from original biological recordings with unknown connectivity. This was obtained in house from a mouse preparation of the spinal cord. Results show that this algorithm can retrieve neurons monosynaptically connected to the target in

simulated datasets within a single run. Iterative and recursive processes can identify monosynaptic neurons and disynaptic neurons under favorable conditions. Application of these processes to the biological dataset gives clues to identify neurons monosynaptically connected to the target. We conclude that the work presented provides substantial proof of concept for the potential use of AI algorithms to the study of effective connectivity.

ROLE OF GABA LEVELS IN MODULATION OF INJURY-INDUCED PAIN

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Aude Charron[1], Lucie Pepino[1], Francis Castets[1], Chiara Salio[2], Aziz Moqrich[3]
[1]AIX MARSEILLE UNIVERSITE, Ibdm-cnrs Umr7288, Marseille cedex, France, [2]University of Turin, Department Of Veterinary Sciences, Turin, Italy, [3]IBDM - Institut de Biologie du Développement de Marseille, Umr 7288, Marseille Cedex, France

Increasing evidence suggests that loss of spinal inhibition (disinhibition) is believed to underlie several forms of chronic pain (Braz et al., 2014; Sandkuhler, 2009; Yaksh, 1989; Zeilhofer et al., 2012). One of the most contested hypotheses proposes that disinhibition is due to loss of a subset of inhibitory interneurons and/or a reduction in γ-aminobutyric acid (GABA) synthesis and release (Castro-Lopes et al., 1993; Hughes and Todd, 2020; Moore et al., 2002; Petitjean et al., 2015; Polgar et al., 2005; Polgar and Todd, 2008). Here, we provide new evidence supporting the importance of spinal GABA contents in modulation of injury-induced mechanical pain. We showed that *Gad1* haplodeficiency, the main GABA synthetizing enzyme, causes a significant decrease of synaptic GABA in both sexes, and that this decrease was more pronounced in female mice. In line with this, GAD haplodeficiency caused an exacerbated formalin-evoked pain selectively in female mice, and both sexes exhibited a prolonged injury-induced mechanical hypersensitivity in both sexes in three different pain models: the Zymosan A as a model of inflammatory pain, the Brennan test as a model of postoperative pain, and the CCI model of neuropathic pain. Our data provide new elements supporting the importance of GABA levels in modulation of injury-induced pain.

DOWNREGULATION OF PARVALBUMIN PROTEIN IN DORSAL HORN INTERNEURONS ELICITS MECHANICAL PAIN HYPERSENSITIVITY.

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Haoyi Qiu, Lois Miraucourt, Hugues Petitjean, Albena Davidova, Reza Sharif-Naeini
McGill University, Physiology, Montreal, Canada

The nervous system processes sensory information through the precise coordination of neuronal networks and their synaptic firing patterns. In the spinal cord, the segregation of touch and pain inputs is mediated in part by the output of a subset of tonic firing inhibitory neurons (PVIN) that express the parvalbumin protein. The parvalbumin protein (PVp) is a calcium (Ca2+)-binding protein that buffers the accumulation of calcium following a train of action potential to allow for tonic firing. Here, using Western blot, qPCR, and immunohistochemistry, we find that nerve injury causes a decrease in PVp expression in PVINs and decreased their inhibitory output, ultimately resulting in mechanical allodynia, where innocuous inputs produce a painful response. We also examined the causality of this observation by reducing PVp in otherwise healthy animals and observe that PVIN lose their ability to fire tonically and the mice develop mechanical allodynia. To directly relate the firing activity of PVIN to mechanical allodynia, we produced a virus consisting of an inhibitory pharmacogenetic tool (hM4D) and an excitatory opsin (oChIEF) inserted in a Cre/FlpO-dependent manner and injected it in in *PV::cre;FLP-tdTomato* mice. Mice were implanted with an optic fiber to deliver pulses of light on the lumbar segment of the spinal cord. The injection of CNO to silence PVIN resulted in mechanical allodynia. However, simultaneous photo-activation of PVIN caused an alleviation of mechanical hypersensitivity. Our results indicate an essential role for PVp-mediated calcium buffering and precise PVIN firing frequency modulation in the development of mechanical allodynia after nerve injury.

[1]Institut des Neurosciences Cellulaires et Intégratives, Team 4: Plasticity Of Pain Control, Strasbourg, France, [2]Université de Strasbourg, Lnca Umr 7364, Ci2n Uar 3489, Strasbourg, France

In the nervous system, specialized sensory neurons (i.e nociceptors) are able to detect internal and external stimuli of various nature and intensity, such as mecanical deformation, heat, cold or irritation caused by chemicals. Peripheral nociceptors make synapses with secondary nuyerons or interneurons of the dorsal horn of the spinal cord where nociceptives information are first integrated then send to the suprapsinal centers centers of pain. Nociceptive informations are mainfly integrated in the superficial layers of the dorsal horn while deeper layers tend to receive a convergence of both nociceptive and non nociceptive informations. It is generally considered that hot nociceptive informations are carried by unmyalinated C fibers while cold informations are perceived by thinly myelinated Aδ fibers. However, how these informations are integrated whithin the spinal cord is still unclear. This study aims to further caracterize the spinal integration of thermal nociceptive inforamtion, specifically by the wide dynamic range neurons of the deep layers that received convergent informations from the periphery. Using a novel peltier thermode allowing a wide range of stimulation in various temprature and duration, we caracterized the response of spinal wide dynamic range neurons after applying various innocuous and noxious thermal stimuli.

MIF INHIBITOR (ISO-1) REDUCES PAIN HYPERSENSITIVITY IN A MODEL OF PERIPHERAL NEUROPATHY

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Monica Pontearso, Pavel Adamek, Jakub Slepicka, Mario Heles, Diana Spicarova, Jiri Palecek
Fyziologický ústav AV ČR, Laboratory Of Pain Research, Prague, Czech Republic

Macrophage migration inhibitory factor (MIF) is a proinflammatory cytokine, and its genetic deletion prevents the development of hypersensitivity induced by peripheral nerve injury or inflammation. MIF exerts its biological functions mainly through binding to the putative membrane receptor, CD74. MIF tautomerase inhibitor (S,R)-3(4-hydroxyphenyl)- 4,5-dihydro-5-isoxazole acetic acid methyl ester (ISO-1) binds to the MIF active site and blocks the MIF-CD74 binding. Our aim was to examine whether systemic treatment with ISO-1 alleviates the hypersensitivity induced by peripheral neuropathy and modulates synaptic transmission at the spinal cord level. Peripheral neuropathy was induced by chronic constriction injury (CCI) of the sciatic nerve. Electronic Von Frey test to assess mechanical sensitivity and patch-clamp recordings of excitatory and inhibitory postsynaptic currents (EPSCs, IPSCs) from superficial dorsal horn neurons in mouse spinal cord slices were used. Inhibitory currents were evoked by optical stimulation of channelrhodopsin expressing inhibitory neurons. Mechanical allodynia induced by CCI was prevented with the ISO-1 treatment. CCI also significantly increased the spontaneous EPSCs frequency and decreased the amplitude of the light-evoked IPSCs in excitatory neurons. The systemic ISO-1 treatment largely diminished these pathological effects on nociceptive synaptic transmission induced by the CCI. Our results suggest that ISO-1 treatment reduces the development of hypersensitivity after nerve injury. One of the underlying mechanisms of the ISO-1 effect could be balancing the CCI-induced changes of excitatory and inhibitory synaptic transmission in the spinal cord dorsal horn.

Dual PI3Kδ/γ Inhibitor Duvelisib Prevents Development of Neuropathic Pain in Model of Paclitaxel-Induced Peripheral Neuropathy.
The development of painful paclitaxel-induced peripheral neuropathy (PIPN) represents a major dose-limiting side effect of paclitaxel chemotherapy. Here we report a promising effect of duvelisib (Copiktra), a novel FDA-approved PI3Kδ/γ isoform-specific inhibitor, in preventing paclitaxel-induced pain-like behavior and pronociceptive signaling in DRGs and spinal cord dorsal horn (SCDH) in rat and mouse model of PIPN. Duvelisib blocked the development of mechanical hyperalgesia in both males and females. Moreover, duvelisib prevented paclitaxel-induced sensitization of TRPV1 receptors, and increased PI3K/Akt signaling in small-diameter DRG neurons and an increase of CD68 cells within DRGs. Specific optogenetic stimulation of inhibitory neurons combined with patch-clamp recording revealed that duvelisib inhibited paclitaxel-induced weakening of inhibitory, mainly glycinergic control on SCDH excitatory neurons. Enhanced excitatory and reduced inhibitory neurotransmission in the SCDH following PIPN was also alleviated by duvelisib application. In summary, duvelisib showed a promising ability to prevent neuropathic pain in PIPN. The potential use of our findings in human medicine may be augmented by the fact that duvelisib is an FDA-approved drug with known side effects. We show that duvelisib, a novel FDA-approved PI3Kδ/γ isoform-specific inhibitor, prevents the development of paclitaxel-induced pain-like behavior in males and females and prevents pronociceptive signaling in DRGs and spinal cord dorsal horn in rat and mouse model of paclitaxel-induced peripheral neuropathy.

PRESYNAPTIC GABAERGIC INHIBITION CONTRIBUTES TO PUNCTATE ALLODYNIA CIRCUITS ACTIVATION IN INFLAMMATORY PAIN

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Sheng Liu
Pharmacology Institute, Heidelberg University, Heidelberg, Germany

Aims: Mechanical allodynia occurs in distinct forms in inflammatory pain, including dynamic and punctate mechanical allodynia. Our previous study indicates presynaptic GABAergic inhibition switches to excitation in nociceptors under inflammatory pain conditions, but contribution of presynaptic inhibition to these distinct mechanical allodynia forms is not clear. Methods: To investigate the role of presynaptic inhibition in these circuits, we generated mice conditionally lacking GABAA receptors in DRG nociceptor (SNS-GABAAβ3-/-). We used an IEG-based dual epoch method to simultaneously visualize the population correlates and the circuitry involved in these two contrasting types of mechanical allodynia in the spinal cord dorsal horn at a single-cell resolution. Results: In conditions of inflammatory pain induced by paw inflammation, SNS-GABAAβ3-/- mice did not develop punctate mechanical allodynia, while dynamic mechanical allodynia was still preserved. We observed that punctate and dynamic mechanical stimuli shape distinct activation patterns of intermingled neurons in the spinal cord dorsal horn under inflammatory pain conditions. Only the neuronal population activated by punctate mechanical stimuli was significantly reduced in SNS-GABAAβ3-/- mice as compared to control littermates. Conclusions: Collectively with our previous studies, these results support the hypothesis that presynaptic GABAergic inhibition switches to excitation in nociceptors under inflammatory pain conditions, and particularly modulates punctate mechanical allodynia. Moreover, this study is amongst the first to visualize the circuit population of these two distinct forms of mechanical allodynia and demonstrates the distinct, but intermingled, patterns shared between them.

INTEGRATIVE ANALYSIS OF DESCENDING PAIN MODULATION PATHWAYS

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Xiaoke Chen, Qian Wang, Gregory Nachtrab
Stanford University, Biology, Stanford, United States of America

Persistent mechanical pain caused by inflammation or nerve injury is a debilitating clinical problem. The spinal cord-projecting neurons in the rostral ventromedial medulla (RVM^{SC}neurons) play active roles in pain facilitation. However, the underlying circuitry and molecular mechanisms remain largely unknown. Here we show that acute activation of $OPRM1^{+}RVM^{SC}$neurons does not facilitate pain in normal mice, but activity of these neurons is required for both initiation and maintenance of mechanical hypersensitivity in mouse models of inflammatory and neuropathic pain. Surprisingly, we find that the lateral superior colliculus rather than the traditionally assumed periaqueductal gray, provides the excitatory input onto the $OPRM1^{+}RVM^{SC}$ neurons that drives mechanical hypersensitivity. Combining Ribotag RNA profiling and pathway manipulation, we establish that collicular inputs are essential for upregulating pseudokinase CaMKv in the $OPRM1^{+}RVM^{SC}$ neurons after nerve injury, and demonstrate that up- or down- regulation of CaMKv is sufficient to drive or reverse mechanical hypersensitivity. Together, our results reveal a collicular-medulla-spinal cord pathway that drives persistent pain and substantiate CaMKv as a key molecular determinant of mechanical hypersensitivity.

Cav3.2 T-type calcium channel is a major molecular actor of neuropathic pain in peripheral sensory neurons, but its involvement at the supra-spinal level is almost unknown. Using the spared nerve injury neuropathic pain model, we combined in vitro/in vivo electrophysiological approaches and behavioral tests in a murine model that allows the identification of the Cav3.2 channels and their conditional deletion in specific areas. We show that in the Anterior Pretectum (APT), a hub of connectivity of the somatosensory system involved in pain perception, Cav3.2 channels are expressed in a sub-population of GABAergic neurons co-expressing parvalbumin (PV). In these PV-expressing neurons, Cav3.2 channels contribute to a high frequency bursting activity, which is increased in mice that undergo the spared nerve injury. Specific deletion of Cav3.2 channels in APT neurons reduced both the initiation and maintenance of mechanical and cold allodynia. These data are a direct demonstration that centrally expressed Cav3.2 channels also play a fundamental role in pain pathophysiology.

INVOLVEMENT OF PARVALBUMIN-POSITIVE GABAERGIC NEURONS IN BASAL FOREBRAIN MODULATION IN A MOUSE MODEL OF NEUROPATHIC PAIN

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Marie-Luise Edenhofer, Michaela Kress, Kai Kummer
Medical University of Innsbruck, Institute Of Physiology, Innsbruck, Austria

Chronic neuropathic pain is a public health issue that affects ~5 % of the European population and is caused by a lesion or disease of the somatosensory system. The central mechanisms underlying the chronification of pain are not yet fully understood. The medial prefrontal cortex receives input from basal forebrain (BF) cholinergic neurons that is altered after nerve injury. Parvalbumin (PV)-positive GABAergic neurons are of special importance for this regulation, as those neurons produce widespread inhibition. To elucidate the role of PV neurons in the pain-associated changes of BF cholinergic neurons, we investigated the electrophysiological properties of BF-PV neurons. PV neurons were selectively labelled and acute brain slices were prepared one week after spared nerve injury (SNI). After SNI, BF-PV neurons demonstrated decreased firing rates in response to depolarizing current injections compared to sham controls. Consistently, the area under the curve (AUC) of the action potential frequency against injected currents was reduced in SNI mice. As postsynaptic transmission can influence the observed decrease in BF-PV neuron excitability, we recorded spontaneous inhibitory (sIPSC) and excitatory (sEPSC) postsynaptic currents. Neurons recorded from brain slices obtained from SNI treated mice demonstrated a reduced frequency of sEPSCs, suggesting a reduction of excitatory inputs. Our findings suggest that alterations in cholinergic synaptic transmission in neuropathic pain may be caused by reduced inhibitory inputs mediated by local BF-PV neurons. In order to elucidate the direct nature of this PV-to-ChAT signaling, we will perform patch-clamp recordings from ChAT neurons in response to optogenetic activation of BF-PV neurons.

Simultaneous scattering compensation at multiple points in multi-photon microscopy.
The two-photon fluorescence imaging depth has been significantly improved in recent years by compensating for tissue scattering with wavefront correction. However, in most approaches the wavefront corrections are valid only over a small sample region on the order of 1 to 10 µm. In samples where most scattering structures are confined to a single plane, sample conjugate correction geometries can increase the observable field to a few tens of µm. Here, we apply a recently introduced fast converging scheme for sensor-less scattering correction termed "Dynamic Adaptive Scattering compensation Holography" (DASH) in a sample conjugate configuration with a high pixel count nematic liquid crystal spatial light modulator (LC-SLM). Using a large SLM allows us to simultaneously correct for scattering at multiple field points, which can be distributed over the entire field of view provided by the objective lens. Despite the comparably slow refresh time of LC-SLMs, we achieve correction times on the order of 10 s per field point, which we show is sufficiently fast to counteract scattering at multiple sites in living mouse hippocampal tissue slices.

Fatty acyl availability modulates cardiolipin composition and alters mitochondrial function in HeLa cells.
The molecular assembly of cells depends not only on the balance between anabolism and catabolism but to a large degree on the building blocks available in the environment. For cultured mammalian cells, this is largely determined by the composition of the applied growth medium. Here, we study the impact of lipids in the medium on mitochondrial membrane architecture and function by combining LC-MS/MS lipidomics and functional tests with lipid supplementation experiments in an otherwise serum-free and lipid-free cell culture model. We demonstrate that the composition of mitochondrial cardiolipins strongly depends on the lipid environment in cultured cells and favors the incorporation of essential linoleic acid over other fatty acids. Simultaneously, the mitochondrial respiratory complex I activity was altered, whereas the matrix-localized enzyme citrate synthase was unaffected. This raises the question on a link between membrane composition and respiratory control. In summary, we found a strong dependency of central mitochondrial features on the type of lipids contained in the growth

medium. This underlines the importance of considering these factors when using and establishing cell culture models in biomedical research. In summary, we found a strong dependency of central mitochondrial features on the type of lipids contained in the growth medium.

EXCITABILITY OF INJURED AND NON-INJURED NEURONS AFTER SPARED NERVE INJURY

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Elena Konnova[1], Alexandru Deftu[2], Paul Chu Sin Chung[1], Guylène Kirschmann[2], Marc Suter[2], Isabelle Decosterd[1,3]
[1]Lausanne University Hospital, Anesthesiology Department - Pain Center, Lausanne, Switzerland, [2]Pain Center, Department Of Anesthesiology, Lausanne, Switzerland, [3]University of Lausanne, Department Of Fundamental Neuroscience, Lausanne, Switzerland

Aims. Various models of neuropathic pain demonstrate that nerve injury leads to hyperexcitability of primary sensory neurons. The spared nerve injury (SNI) model produces a close arrangement of injured and non-injured primary sensory neurons within the same dorsal root ganglion (DRG). We aim to distinguish the excitability of injured and non-injured of primary sensory neurons after SNI. Methods. We used transgenic B6-Tg(ATF3::GFP)Wlf mice that express GFP under the promoter of ATF3, highly upregulated by axonal injury and used as marker of injured neurons. Non-injured neurons from the spared sural nerve were labelled using retrograde tracer FastBlue (FB). ATF3+ and FB+ neurons were sorted by FACS. Extracellular electrophysiological recordings were perfomed using multi-electrode arrays (MEA) at 2, 4, 7 and 14 days after SNI. Whole-cell patch clamp recordings of DRG neurons were performed to reveal changes in current-evoked excitability. Results. The MEA recordings indicated an increased spontaneous activity in the ATF3+ injured neurons at the different timepoints after SNI. The FB+ non-injured neurons showed an increase only 2 days after SNI. In the patch clamp recordings, the ipsilateral FB+ neurons showed a higher firing frequency rate than the contralateral FB+ neurons. ATF3+ neurons only showed a different firing pattern, as illustrated by the change in different AP features. Conclusions. Hyperexcitability is present with different patterns in injured and adjacent non-injured DRG neurons after SNI. This study suggests that injured neurons are more prone to fire spontaneously, while non-injured neurons are hypersensitive to stimulation.

CONTRIBUTION OF PERIPHERAL NEURONAL ACTIVITY TO SPINAL MICROGLIAL REACTIVITY IN CHRONIC PAIN

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Manon Isler, Guylène Kirschmann, Isabelle Decosterd, Marc Suter
Pain Center, Department Of Anesthesiology, Lausanne, Switzerland

Chronic neuropathic pain is a complex pathology with a strong neuroimmune interplay. Abnormal peripheral activity arriving from primary sensory neurons of the dorsal root ganglia (DRG) contributes to spinal microglia reactivity after nerve injury and previous studies in rats demonstrated that electrical stimulation of the peripheral nerve induces spinal microglial activation. Our aim is to further investigate the contribution of nociceptive and non-nociceptive inputs to spinal microglial reactivity in the context of chronic pain. Method: we first performed electrical stimulation on the sciatic nerve in CX3CR1-eGFP mice. 2 days after stimulation, we quantified GFP signal density and cell proliferation (Ki-67) using immunohistochemistry on L3-L5 dorsal horn. Then, we used optogenetic tools and blue light was applied onto sciatic nerve to selectively activate all fiber types with Advilin-Cre/ChR2-TdTomato mice or nociceptive fibers only in SNS-Cre/ChR2-TdTomato mice. Results: we observe microglial reactivity in the spinal cord after electrical and optogenetic stimulation when compared to the controls ($p=0.0199$). Similarly, light activation of Advilin-ChR2 nociceptive and non-nociceptive neurons induces microglial reactivity in the spinal cord. Activation of SNS-ChR2 nociceptive neurons only induces also microglial reactivity. Conclusion: intense activity from nociceptive neurons is sufficient to induce spinal microglia reactivity. Same experiments performed in non-nociceptive ChR2 transgenic lines will allow us to determine whether the activation of nociceptive fibers is not only sufficient but also necessary for the development of neuroinflammation and neuropathic pain.

THE PARABRACHIAL NUCLEUS TO THE CENTRAL AMYGDALA SYSTEM REGULATES LONG-LASTING WIDESPREAD SENSITIZATION IN THE RODENT MODEL OF NOCIPLASTIC PAIN

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Manami Yajima, Takao Okuda, Naoko Sato, Yukari Takahashi, Fusao Kato
Jikei University School of Medicine, Neuroscience, Tokyo, Japan

Widespread sensitization is one of the hallmark symptoms of nociplastic pain, characterized by augmented nociception at various body sites not necessarily associated with injury/inflammation. We have demonstrated that inflammation in a trigeminally innervated region results in robust expression of c-fos protein in the bilateral parabrachial nucleus (PBN) and the right central amygdala (CeA), and this excitation was accompanied by bilateral hindpaw sensitization in a manner critically dependent on CeA neuronal activity (Sugimoto et al, 2021; Miyazawa et al, 2018). Here we asked whether the PBN-CeA network plays specific roles in this formalin-induced long-lasting sensitization. Single-injection of formalin into the left upper lip decreased the bilateral paw withdrawal threshold for >10 days, and this sensitization was counteracted by intraperitoneal administration of 30 mg/kg pregabalin. The PBN neurons activated in this model were visualized and selectively stimulated using FosTRAP mice and AAV-mediated transfection of ChR2 into the PBN and CeA. The activated CeA neurons showed a higher incidence of postsynaptic responses to light-evoked stimulation of the fibers arising from the activated PBN neurons than those from the general population of PBN neurons. These observations indicate that PBN neurons and CeA neurons form specific robust connections that regulate CeA neuronal activity and thus modulate the expression of widespread sensitization.

ROLE OF VOLTAGE-DEPENDENT POTASSIUM CURRENTS ON TRIGEMINAL NEUROPATHIC PAIN

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Ana Abreu, Beatriz Szwarc, André Bastos, Pedro Lima
Sea4Us, Physiology Lab, Lisboa, Portugal

Neuropathic pain affecting the orofacial area is extremely debilitating and remains a therapeutic challenge. Conditions caused by trigeminal nerve injury are characterised by a state of hyperexcitability throughout all levels of the trigeminal axis. This work aimed to characterise the electrophysiological properties of the most peripheral element of this axis, by studying the potassium currents recorded from small-diameter neurones isolated from the trigeminal ganglion of animals with chronic constriction of the infraorbital nerve (CCI-ION) and comparing them to those recorded from naïve animals. The CCI-ION model was induced on female Wistar rats by ligation of a distal segment of the infraorbital nerve, exposed through a small facial incision. The mechanical sensitivity threshold of the ipsilateral whisker pad was reduced for up to 28 days. After this period, the trigeminal ganglia were harvested and dissociated. When compared with neurones from naïve rats, the activation of the potassium channels became more voltage-dependent, and the slower current component became more easily activated, with a hyperpolarized profile. The voltage dependence of inactivation was also altered with surgery: a current component with slower inactivation became more prominent and more voltage-sensitive in the neurons isolated from CCI-ION rats. Combined, these changes lead to increased activity of the potassium voltage-dependent channels, which might represent a mechanism necessary to sustain the higher activity rate typical of the chronic pain state. Such results agree with previous findings on a model of chronic inflammatory orofacial pain and the CCI model of the sciatic nerve.

The hypothalamic neuropeptide, oxytocin (OT), exerts prominent analgesic effects via central and peripheral action. Here we discovered a novel subset of OT neurons whose projections preferentially terminate on OT receptor (OTR)-expressing neurons in the ventrolateral periaqueductal gray (vlPAG). Using a newly generated line of transgenic rats (OTR-IRES-Cre), we determined that most of the vlPAG OTR expressing cells being targeted by OT projections are GABAergic in nature. Both optogenetically-evoked axonal OT release in the vlPAG as well as chemogenetic activation of OTR vlPAG neurons results in a long-lasting overall increase of vlPAG neuronal activity. This then leads to an indirect suppression of sensory neuron activity in the spinal cord and strong analgesia. Finally, we describe a novel OT→vlPAG→spinal cord circuit that seems critical for analgesia in the context of both inflammatory and neuropathic pain.

REPROGRAMMING THE TOPOLOGY OF THE NOCICEPTIVE CIRCUIT IN C. ELEGANS RESHAPES SEXUAL BEHAVIOR

POSTER SESSION 06 - SECTION: PHYSIOLOGY OF PAIN CIRCUITS

Vladyslava Pechuk, Gal Goldman, Yehuda Salzberg, Elad Schneidman, Meital Oren-Suissa
Weizmann Institute of Science, Brain Sciences, Rehovot, Israel

In sexually reproducing species, males and females respond to environmental sensory cues and transform the input into sexually dimorphic traits. Yet, how sexually dimorphic behavior is encoded in the nervous system is poorly understood. We characterize the sexually dimorphic nociceptive behavior in *C. elegans* – hermaphrodites present a lower pain threshold than males in response to aversive stimuli, and study the underlying neuronal circuits, which are composed of the same neurons that are wired differently. By imaging receptor expression, calcium responses and glutamate secretion, we show that sensory transduction is similar in the two sexes, and therefore explore how downstream network topology shapes dimorphic behavior. We generated a computational model that replicates the observed dimorphic behavior, and used this model to predict simple network rewirings that would switch the behavior between the sexes. We then showed experimentally, using genetic manipulations, artificial gap junctions, automated tracking and optogenetics, that these subtle changes to male connectivity result in hermaphrodite-like aversive behavior *in-vivo*, while hermaphrodite behavior was more robust to perturbations. Strikingly, when presented with aversive cues, rewired males were compromised in finding mating partners, suggesting that the network topology that enables efficient avoidance of noxious cues would have a reproductive "cost". To summarize, we present a deconstruction of a neural circuit design that controls sexual behavior, and how to reprogram it. More broadly, our results are an example of how common neuronal circuits changed their function during evolution by subtle topological rewirings to account for different environmental and sexual needs.

Synaptic Protein Degradation Controls Sexually Dimorphic Circuits through Regulation of DCC/UNC-40.
Sexually dimorphic circuits underlie behavioral differences between the sexes, yet the molecular mechanisms involved in their formation are poorly understood. We show here that sexually dimorphic connectivity patterns arise in C. elegans through local ubiquitin-mediated protein degradation in selected synapses of one sex but not the other. Specifically, synaptic degradation occurs via binding of the evolutionary conserved E3 ligase SEL-10/FBW7 to a phosphodegron binding site of the netrin receptor UNC-40/DCC (Deleted in Colorectal Cancer), resulting in degradation of UNC-40. In animals carrying an undegradable unc-40 gain-of-function allele, synapses were retained in both sexes, compromising the activity of the circuit without affecting neurite guidance. Thus, by decoupling the synaptic and guidance functions of the netrin pathway, we reveal a critical role for dimorphic protein degradation in controlling neuronal connectivity and activity. Additionally, the interaction between SEL-10 and UNC-40 is necessary not only for sex-specific synapse pruning, but also for other synaptic functions. These findings provide insight into the mechanisms that generate sex-specific differences in neuronal connectivity, activity, and function.

DYNAMIC GATING OF PERCEPTUAL FLEXIBILITY BY DIVERSE CORTICAL RESPONSES

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Blake Sidleck, Priya Agarwal, Jack Toth, Danyall Saeed, Dylan Leonard, Michele Insanally
University of Pittsburgh School of Medicine, Departments Of Otolaryngology, Neurobiology, Pittsburgh, United States of America

The ability to flexibly adapt to changing environments is the hallmark of an adaptive nervous system and is seen in animals across the entire phylogenetic tree. This is in stark contrast to perceptual and cognitive inflexibility which is implicated in many neurological disorders including hearing loss, autism, and schizophrenia. While sensory and frontal cortical areas have long been implicated in flexible behaviors, we lack a fundamental understanding of how information is gated within these circuits to select and update behavioral strategies based on sensory input and context. We trained mice to perform a go/no-go auditory reversal learning task that required animals to adapt their behavioral response to the same set of auditory cues. Specifically, animals were trained to respond to a target tone (11.2 kHz) and to withhold from responding to a nontarget tone (5.6 kHz) for water reward. Once animals learned this phase of the task we then implemented a rule-switch and reversed which tone was rewarded, requiring animals to remap stimulus-reward contingencies. Chemogenetic silencing demonstrated that auditory cortex is required for reversal learning in mice. Using silicon probe recordings, we simultaneously monitored the activity of 1,322 single-units in auditory cortex (AC) and 1,381 single-units in frontal cortex (M2) during reversal learning. We found that neural response profiles during learning were highly heterogeneous ranging from highly-reliable or ‘classical’ responses to seemingly-random ‘non-classical’ firing. Neural populations in both regions dynamically altered their response profiles during different phases of learning allowing for the emergence of flexible behaviors.

IMAGING THE MOUSE DEVELOPING AUDITORY CORTEX

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Chiara La Rosa[1,2], Stefano Zucca[1,2], Paolo Peretto[1,2], Tommaso Fellin[3], Serena Bovetti[1,2]
[1]University of Turin, Neuroscience Institute Cavalieri Ottolenghi, Torino, Italy, [2]University of Turin, Department Of Life Sciences And Systems Biology, Torino, Italy, [3]Istituto Italiano di Tecnologia, Optical Approaches To Brain Function Laboratory, Genova, Italy

During postnatal development, sensory experiences shape neural connections and individuals acquire memory of these sensory cues. Among the variety of sensory stimuli at which newborn mice are exposed during development, paternal ultrasound vocalizations (USVs) play an important role in forming memories of conspecifics that are recalled in adulthood females to influence mate choice. However, how paternal USVs influence the functional development of cortical auditory circuits is unknown. Here, we performed in vivo two-photon functional imaging and characterized spontaneous activity of layer 2/3 (L2/3) neurons in the primary auditory areas of anaesthetized mice at different postnatal ages, in animals raised with or without their father. P0 mice were injected in auditory cortex with adeno-associated viral vectors expressing GCaMP7 and spontaneous activity was characterized at three developmental time windows: i) P8-P11: when the external auditory canal is closed; ii) P12-P14: when the onset of hearing occurs; iii) P15-P21: during the critical period for hearing. At P8-P11, L2/3 neurons showed spontaneous synchronous transients. From hearing onset, a switch from synchronous to asynchronous activity occurred and, at the end of the critical period, most cells displayed asynchronous largely decorrelated neuronal activity. Interestingly, during the critical period, animals raised in the absence of their father showed significant more correlated activity compared to those raised in the presence of the father. Overall, these results suggest a relevant role of sensory stimuli linked to the developmental presence of the father in shaping auditory circuits.

Phylogenetic variation in cortical layer II immature neuron reservoir of mammals.
The adult mammalian brain is mainly composed of mature neurons. A limited amount of stem cell-driven neurogenesis persists in postnatal life and is reduced in large-brained species. Another source of immature neurons in adult brains is cortical layer II. These cortical immature neurons (cINs) retain developmentally undifferentiated states in adulthood, though they are generated before birth. Here, the occurrence, distribution and cellular features of cINs were systematically studied in 12 diverse mammalian species spanning from small-lissencephalic to large-gyrencephalic brains. In spite of well-preserved morphological and molecular features, the distribution of cINs was highly heterogeneous, particularly in neocortex. While virtually absent in rodents, they are present in the entire neocortex of many other species and their linear density in cortical layer II generally increased with brain size. These findings suggest an evolutionary developmental mechanism for plasticity that varies among mammalian species, granting a reservoir of young cells for the cerebral cortex.

Brain Structural Plasticity: From Adult Neurogenesis to Immature Neurons.
Brain structural plasticity is an extraordinary tool that allows the mature brain to adapt to environmental changes, to learn, to repair itself after lesions or disease, and to slow aging. A long history of neuroscience research led to fascinating discoveries of different types of plasticity, involving changes in the genetically determined structure of nervous tissue, up to the ultimate dream of neuronal replacement: a stem cell-driven "adult neurogenesis" (AN). Yet, this road does not seem a straight one, since mutable dogmas, conflicting results and conflicting interpretations continue to warm the field. As a result, after more than 10,000 papers published on AN, we still do not know its time course, rate or features with respect to other kinds of structural plasticity in our brain. The solution does not appear to be behind the next curve, as differences among mammals

reveal a very complex landscape that cannot be easily understood from rodents models alone. By considering evolutionary aspects, some pitfalls in the interpretation of cell markers, and a novel population of undifferentiated cells that are not newly generated [immature neurons (INs)], we address some conflicting results and controversies in order to find the right road forward. We suggest that considering plasticity in a comparative framework might help assemble the evolutionary, anatomical and functional pieces of a very complex biological process with extraordinary translational potential.

Newly Generated and Non-Newly Generated "Immature" Neurons in the Mammalian Brain: A Possible Reservoir of Young Cells to Prevent Brain Aging and Disease?
Brain plasticity is important for translational purposes since most neurological disorders and brain aging problems remain substantially incurable. In the mammalian nervous system, neurons are mostly not renewed throughout life and cannot be replaced. In humans, the increasing life expectancy explains the increase in brain health problems, also producing heavy social and economic burden. An exception to the "static" brain is represented by stem cell niches leading to the production of new neurons. Such adult neurogenesis is dramatically reduced from fish to mammals, and in large-brained mammals with respect to rodents. Some examples of neurogenesis occurring outside the neurogenic niches have been reported, yet these new neurons actually do not integrate in the mature nervous tissue. Non-newly generated, "immature" neurons (nng-INs) are also present: Prenatally generated cells continuing to express molecules of immaturity (mostly shared with the newly born neurons). Of interest, nng-INs seem to show an inverse phylogenetic trend across mammals, being abundant in higher-order brain regions not served by neurogenesis and providing structural plasticity in rather stable areas. Both newly generated and nng-INs represent a potential reservoir of young cells (a "brain reserve") that might be exploited for preventing the damage of aging and/or delay the onset/reduce the impact of neurological disorders.

Brain Plasticity in Mammals: An Example for the Role of Comparative Medicine in the Neurosciences.
Comparative medicine deals with similarities and differences between veterinary and human medicine. All mammals share most basic cellular and molecular mechanisms, thus justifying murine animal models in a translational perspective; yet "mice are not men," thus some biases can emerge when complex biological processes are concerned. Brain plasticity is a cutting-edge, expanding topic in the field of Neurosciences with important translational implications, yet, with remarkable differences among mammals, as emerging from comparative studies. In particular, adult neurogenesis (the genesis of new neurons from brain stem cell niches) is a life-long process in laboratory rodents but a vestigial, mostly postnatal remnant in humans and dolphins. Another form of "whole cell" plasticity consisting of a population of "immature" neurons which are generated prenatally but continue to express markers of immaturity during adulthood has gained interest more recently, as a reservoir of young neurons in the adult brain. The distribution of the immature neurons also seems quite heterogeneous among different animal species, being confined within the paleocortex in rodents while extending into neocortex in other mammals. A recent study carried out in sheep, definitely showed that gyrencephalic, large-sized brains do host higher amounts of immature neurons, also involving subcortical, white, and gray matter regions. Hence, "whole cell" plasticity such as adult neurogenesis and immature neurons are biological processes which, as a whole, cannot be studied exclusively in laboratory rodents, but require investigation in comparative medicine, involving large-sized, long-living mammals, in order to gain insights for translational purposes.

Clusters of DCX+ cells "trapped" in the subcortical white matter of early postnatal Cetartiodactyla (Tursiops truncatus, Stenella coeruloalba and Ovis aries).
The cytoskeletal protein doublecortin (DCX) is a marker for neuronal cells retaining high potential for structural plasticity, originating from both embryonic and adult neurogenic processes. Some of these cells have been described in the subcortical white matter of neonatal and postnatal mammals. In mice and humans it has been shown they are young neurons migrating through the white matter after birth, reaching the cortex in a sort of protracted neurogenesis. Here we show that DCX+ cells in the white matter of neonatal and young Cetartiodactyla (dolphin and sheep) form large clusters which are not newly generated (in sheep, and likely neither in dolphins) and do not reach the cortical layers, rather appearing "trapped" in the white matter tissue. No direct contact or continuity can be observed between the subventricular zone region and the DCX+ clusters, thus indicating their independence from any neurogenic source (in dolphins further confirmed by the recent demonstration that periventricular neurogenesis is inactive since birth). Cetartiodactyla include two orders of large-brained, relatively long-living mammals (cetaceans and artiodactyls) which were recognized as two separate monophyletic clades until recently, yet, despite the evident morphological distinctions, they are monophyletic in origin. The brain of Cetartiodactyla is characterized by an advanced stage of development at birth, a feature that might explain the occurrence of "static" cell

clusters confined within their white matter. These results further confirm the existence of high heterogeneity in the occurrence, distribution and types of structural plasticity among mammals, supporting the emerging view that multiple populations of DCX+, non-newly generated cells can be abundant in large-brained, long-living species.

Non-Newly Generated, "Immature" Neurons in the Sheep Brain Are Not Restricted to Cerebral Cortex.
A newly proposed form of brain structural plasticity consists of non-newly generated, "immature" neurons of the adult cerebral cortex. Similar to newly generated neurons, these cells express the cytoskeletal protein Doublecortin (DCX), yet they are generated prenatally and then remain in a state of immaturity for long periods. In rodents, the immature neurons are restricted to the paleocortex, whereas in other mammals, they are also found in neocortex. Here, we analyzed the DCX-expressing cells in the whole sheep brain of both sexes to search for an indicator of structural plasticity at a cellular level in a relatively large-brained, long-living mammal. Brains from adult and newborn sheep (injected with BrdU and analyzed at different survival times) were processed for DCX, cell proliferation markers (Ki-67, BrdU), pallial/subpallial developmental origin (,), and neuronal/glial antigens for phenotype characterization. We found immature-like neurons in the whole sheep cortex and in large populations of DCX-expressing cells within the external capsule and the surrounding gray matter (claustrum and amygdala). BrdU and Ki-67 detection at neonatal and adult ages showed that all of these DCX cells were generated during embryogenesis, not after birth. These results show that the adult sheep, unlike rodents, is largely endowed with non-newly generated neurons retaining immature features, suggesting that such plasticity might be particularly important in large-brained, long-living mammals. Brain plasticity is important in adaptation and brain repair. Structural changes span from synaptic plasticity to adult neurogenesis, the latter being highly reduced in large-brained, long-living mammals (e.g., humans). The cerebral cortex contains "immature" neurons, which are generated prenatally and then remain in an undifferentiated state for long periods, being detectable with markers of immaturity. We studied the distribution and developmental origin of these cells in the whole brain of sheep, relatively large-brained, long-living mammals. In addition to the expected cortical location, we also found populations of non-newly generated neurons in several subcortical regions (external capsule, claustrum, and amygdala). These results suggests that non-neurogenic, parenchymal structural plasticity might be more important in large mammals with respect to adult neurogenesis.

SILENT MOVIES SYNCHRONIZE SECONDARY AUDITORY CORTICES MORE IN EARLY DEAF THAN HEARING INDIVIDUALS.

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Maria Zimmermann[1], Rhodri Cusack[2], Marina Bedny[3], Marcin Szwed[1]
[1]Jagiellonian University, Department Of Psychology, Kraków, Poland, [2]Trinity College Dublin, Institute Of Neuroscience, Dublin, Ireland, [3]John Hopkins University, Department Of Psychological And Brain Sciences, Baltimore, United States of America

The auditory cortex of deaf individuals is responsive to a range of tasks in the visual modality. Still, the nature and extent of this repurposing is not well understood. Here naturalistic stimuli were used to elicit neural synchrony in early deaf (n=21) and hearing individuals (n=22). Participants passively watched a silent animated movie (The triplets of Belleville) and three distorted versions of the same film that disrupted its meaning: two piecewise-scrambled versions lacking a coherent plot (12 sec and 2 second scrambled,) and one visually distorted (diffeomorphic, lacking any meaning). In both groups, early visual cortices were synchronized to a similar degree across stimulus types, while higher-cognitive areas (e.g., Precuneus, Superior Parietal Lobule and Prefrontal Cortex) were more synchronized by the intact, meaningful version of the movie. Secondary auditory cortices, along the extent of the superior temporal sulcus (STS), exhibited higher synchrony in deaf than in hearing participants across all stimulus types, with larger effects in the right hemisphere and little synchrony in A1. Meaningful stimulus elicited a significantly higher STS synchronization across deaf individuals than all three scrambled conditions. In the absence of early auditory experience, the STS is engaged by meaningful visual narratives.

The extraction of specific sound features from a complex acoustic environment is essential for orientation, social interaction, and surviving in everyday life. Loss-of-function mutations in the Cacna2d3 gene, encoding the $\alpha_2\delta3$ auxiliary subunit of voltage-gated calcium channels, lead to structural and functional impairments of several auditory nuclei, which are accompanied by deficits on the behavioral level. Albeit being able to distinguish simple pure tones from each other, $\alpha_2\delta3$-KO mice fail to discriminate between amplitude modulated tones (Pirone et al. (2014)). Furthermore, mutations in the *Cacna2d3* gene have been associated with autism spectrum disorder in humans. We here investigated neuronal network activity in the auditory cortex (ACx) of $\alpha_2\delta3$-KO mice and controls. 13 days after the injection of AAV1-hSyn1-jGCaMP7f we performed two-photon calcium imaging of neurons in layer 2/3 of the ACx in awake animals while presenting different sets of acoustic stimuli in a passive listening task. Best frequency (BF) distribution analysis showed no differences in the overall BF distribution but revealed a lower local heterogeneity in $\alpha_2\delta3$-KO mice. Correlation-based clustering of neuronal activity during stimulation with various animal vocalizations displayed no difference between genotypes regarding the number of clusters formed, as well as the number of neurons per cluster. Notably, physical distances between cells in clusters in KO animals were smaller compared to controls, indicating an altered topographic organization of local cells which was independent of stimulus complexity. We also observed subfield-specific changes in population activity, which might provide an explanation for impaired auditory-related learning in $\alpha_2\delta3$-KO mice.

Surround suppression (SS) is a fundamental property of all sensory systems. However, only limited portions of its landscape have been studied. In the auditory system, a one dimensional array of hair cells corresponds to the full spectral contents of all sounds. We exploited the simplicity of this 1D representation of sounds to investigate the full landscape of SS. We recorded single unit spiking from the auditory cortex (ACx) of awake mice in response to an array of spectrally broadband auditory stimuli with varying central frequencies and bandwidths. We recorded 88 auditory neurons from 5 mice using Neuropixels probes. Our recordings revealed a novel response profile to the full frequency-bandwidth array of sounds, with a majority of neurons preferring larger bandwidths for lower frequencies. To gain insight into the possible mechanism of these responses, we modelled neuronal responses using a novel function called Modulated Ricker Wavelet (MRW) which is a variation of the “Mexican hat” function often used to model SS. Using MRW, we were able explain the response properties of single neurons with remarkable accuracy (often >>90%). We show that these highly prevalent responses in ACx, result from simple rules of lateral inhibitory sidebands in frequencies above the excitatory band of the neuron. Our data implies robust over-representation of top edges in the ACx and may form the mechanistic basis of auditory edge detection and possibly other computations relating to modulations in the spectral content of sounds.

BEHAVIORAL AND NEURAL CORRELATES OF EARLY MUSIC EXPOSURE IN MICE

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Kamini Sehrawat, Israel Nelken
The Hebrew University of Jerusalem, Edmond And Lily Safra Center For Brain Sciences, Jerusalem, Israel

The natural auditory environment consists of complex sounds. One interesting family of complex sounds is human music, a remarkably complex acoustic set of stimuli with a dynamic spectrotemporal structure. In recent years, the study of music preferences in humans has substantially advanced, with evidence for significant brain activity evoked in the auditory cortex as well as in reward areas. However, our understanding of the connections between the auditory and reward systems is limited. Several studies suggested that rodents show idiosyncratic preferences to human music and can be conditioned to prefer specific musical pieces. Therefore, we use the rodent model to investigate the neural mechanisms that may underlie music preferences. To this aim, we exposed young C57BL/6 mice (P7-P40) to a musical environment consisting of excerpts from Beethoven's symphony no. 9. I tested their sound preference as young adults. Exposed mice showed a significant preference for the music to which they were exposed over silence relative to control and naive mice, but this preference habituated on further tests. These effects showed sex effects, with males showing stronger preferences to the exposed music than females. We performed wide-field calcium imaging to measure neural response to different sounds in the auditory cortex, including excerpts from the music the animals were exposed to in their infancy. The results indicate suppression of the overall activity of the auditory cortex in exposed animals compared to the control/naive animals.

The Claustrum Supports Resilience to Distraction.
A barrage of information constantly assaults our senses, of which only a fraction is relevant at any given point in time. However, the neural circuitry supporting the suppression of irrelevant sensory distractors is not completely understood. The claustrum, a circuit hub with vast cortical connectivity, is an intriguing brain structure, whose restrictive anatomy, thin and elongated, has precluded functional investigation. Here, we describe the use of Egr2-CRE mice to access genetically defined claustral neurons. Utilizing conditional viruses for anterograde axonal labeling and retrograde trans-synaptic tracing, we validated this transgenic model for accessing the claustrum and extended the known repertoire of claustral input/output connectivity. Addressing the function of the claustrum, we inactivated CL neurons, chronically as well as acutely, in mice performing an automated two-alternative forced-choice behavioral task. Strikingly, inhibition of CL neurons did not significantly impact task performance under varying delay times and cue durations, but revealed a selective role for the claustrum in supporting performance in the presence of an irrelevant auditory distractor. Further investigation of behavior, in the naturalistic maternal pup-retrieval task, replicated the result of sensitization to an auditory distractor following inhibition of CL neurons. Initiating investigation into the underlying mechanism, we found that activation of CL neurons modulated cortical sensory processing, suppressing tone representation in the auditory cortex. This functional study, utilizing selective genetic access, implicates the claustrum in supporting resilience to distraction, a fundamental aspect of attention.

HUMAN CORTICAL AUDITORY PROCESSING OF NATURALISTIC SPEECH WITH SIMULATED HEARING LOSS: A DATA-DRIVEN FMRI APPROACH

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Arkan Al-Zubaidi, Jochem Rieger
University of Oldenburg, Applied Neurocognitive Psychology Lab, Oldenburg, Germany

We investigate the cortical auditory processing of realistic speech in natural soundscapes with clear and degraded naturalistic stimuli using voxel-wise encoding models (VWEMs), where acoustic features are used to model brain activity. We used an audio description of the movie "Forrest Gump" soundtrack as a clear naturalistic stimulus (CS) and, in addition, in two versions with different levels of acoustic degradation (low (S2) and high (N4), Bisgaard et al., 2010) at higher frequencies to simulate common types of hearing loss. We measured fMRI responses while normal-hearing participants listened to the full movie in each session but in eight segments at different levels of degradation and the three repetitions at different degradation levels (CS, S2, or N4) distributed over three sessions. We estimated VWEMs for the sound Mel-frequencies spectrogram of CS, S2, and N4 stimuli separately. The speech perception was best for CS, intermediate for S2, and worst for N4 stimuli. In contrast, the VWEMs in early auditory cortices best predicted the BOLD-responses in N4 compared to CS and S2 conditions. In the N4 condition, we found the highest correlations between predicted and observed BOLD-responses in Heschl's gyrus, planum temporale and the superior temporal gyrus. Our results demonstrate that the neural processes underlying the processing of speech in natural soundscapes are better captured by Mel-spectrogram in the core auditory areas when the speech is acoustically degraded. This suggests an interaction between the intelligibility of speech in natural soundscapes and the processing of acoustic features in early auditory cortices.

Enzymatic removal of the extracellular matrix (ECM) is increasingly recognized to promote learning, memory recall, and restorative plasticity. The impact of the ECM on translaminar dynamics during cortical circuit processing is still not understood. We removed the ECM in the primary auditory cortex of Mongolian gerbils using local injections of hyaluronidase (HYase). Using current-source density (CSD) analysis, we found layer-specific changes of the spatiotemporal synaptic activity patterns with increased corticocortical integration in supragranular layers with simultaneous weakening of early local sensory input processing within infragranlar layers. The spatiotemporal changes were associated with an oscillatory fingerprint in the beta-band (25-36 Hz) within infragranular layers. To understand the laminar interaction dynamics after ECM digestion, we used time-domain conditional Granger causality (GC) measures, revealing a stronger drive from supragranular layers into late infragranular layer, which also showed increased drive towards early infragranular layer. These results show that ECM degradation caused an altered translaminar cortical network dynamic with stronger supragranular lead of the columnar response profile and increased cross-columnar frequency integration. We further described that behavioral auditory training leads to transient downregulation of the ECM protein brevican in auditory cortex. Brevican degradation has been shown to depend on dopaminergic neuromodulation via activation of the protease ADAMTS-4/5. Our hypothesis is that during acquisition learning, dopamine release triggers an initial downregulation of the ECM to optimize the dynamics of corticocortical networks for synaptic plasticity. We speculate that such learning-dependent regulation of the ECM needs concomitant action of reinforcing dopaminergic neuromodulation coding the behavioral relevance of events.

THE SYNAPTIC ORIGINS AND FUNCTIONAL ROLE OF DIVERSE CORTICAL RESPONSES DURING BEHAVIOR

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Badr Albanna[1], Jack Toth[2], Brian Depasquale[3], Saba Shokat Fadaei[4], Trisha Gupta[2], Kishore Kuchibhotla[5], Kanaka Rajan[6], Robert Froemke[4,7], Michele Insanally[2]
[1]University of Pittsburgh, Department Of Neuroscience, Pittsburgh, United States of America, [2]University of Pittsburgh School of Medicine, Departments Of Otolaryngology, Neurobiology, Pittsburgh, United States of America, [3]Princeton University, Princeton Neuroscience Institute, Princeton, United States of America, [4]New York University School of Medicine, Skirball Institute, New York, United States of America, [5]Johns Hopkins University, Department Of Psychological And Brain Sciences, Baltimore, United States of America, [6]Icahn School of Medicine at Mount Sinai, Friedman Brain Institute, New York, United States of America, [7]New York University, Center For Neural Science, New York, United States of America

Neuronal responses during behavior are diverse, ranging from highly reliable ‘classical’ responses to irregular or seemingly-random ‘non-classically responsive’ firing. Various spiking patterns (or lack thereof) have been documented throughout brain regions in response to different sensory inputs, in relation to decision making, motor actions, or other task-related signals. While this continuum of response properties is frequently observed, little is known about the synaptic origins and contributions of diverse response profiles to network function, perception, and behavior. Previous work used a novel single-trial, spike-timing-based analysis to show that both classically and non-classically responsive cortical neurons contain significant information about sensory stimuli and behavioral decisions suggesting that non-classically responsive cells may play an underappreciated role in perception and behavior. Here we use a task-performing, spiking recurrent neural network model incorporating spike-timing-dependent plasticity that captures heterogeneous responses measured from auditory cortex of behaving rodents. We leverage this model to explore the synaptic origin and functional contribution of heterogeneous response profiles. Detailed inactivation experiments revealed that classically and non-classically responsive units contributed to task performance via output and recurrent connections, respectively, providing evidence for a double-dissociative function of these subpopulations. Non-classically responsive units also constrained network dimensionality by regulating correlations across the network. Excitatory and inhibitory plasticity was required to shape spiking responses and task performance. Local synaptic patterns derived from model units predicted responses of auditory cortical neurons from *in vivo* whole-cell recordings during behavior. Our results indicate that potentially any neuron might be important for task performance, regardless of classical response properties.

AGE-RELATED CHANGES IN AUDITORY CORTICAL PROCESSING

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Sarah Fouda[1], Shuzo Sakata[2]
[1]University of Strathclyde, Sibps, Glasgow, United Kingdom, [2]University of Strathclyde, Sipbs, Glasgow, United Kingdom

Aging is inevitable. It leads to deficits across various brain functions, including sensory domains. However, we know little about how aging can modify neural computations at the cellular and neural circuit levels. To address this issue, we investigated spontaneous activity in the mouse auditory cortex (AC) across age. Specifically, we compared neural activity in mice on C57BL/6 background ("C57") with F1 hybrid of C57BL/6 and CBA/Ca backgrounds ("Hybrid"). The former is known as a model of early age-related hearing loss, due to a genetic deficit at the cochlear level, whereas the latter does not exhibit such hearing loss. Thus, comparing these two strains allows to evaluate peripheral and central contributions of aging processes in the auditory system. We observed age-related and strain-specific changes in the activity of putative excitatory neurons in the AC: hybrid mice exhibited a steady reduction in their firing rate as age whereas spontaneous firing rate in C57 mice increased as age. We quantified the efficiency of individual spike trains by calculating an information theoretic metric, called contrast entropy. We found that although C57 mice did not show age-related change, hybrid mice exhibited a U-shape trend, namely contrast entropy significantly reduced only during the adult period, but not during the old period, compared to that during the young period. We suggest that peripheral and central aging processes have distinct impacts on the capacity of auditory cortical processing.

RAPID PLASTICITY IN THE INFERIOR COLLICULUS OF AWAKE, FREELY MOVING MICE

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Alexa Buck[1], Olivier Postal[2], Typhaine Dupont[1], Nicolas Michalski*[1], Boris Gourévitch[1]

Neural plasticity was previously thought to only occur during developmental but substantial evidence has since shown plastic changes are possible in the adult brain. However, the nature of this underlying plasticity remains largely unknown. Evidence of transient adult plasticity has been demonstrated to largely depend on input, specifically auditory exposure in the auditory cortex (Norena et al, 2006). There is also evidence that task specific adaptations are similarly represented, and in fact originate in the auditory midbrain, specifically the inferior colliculus (IC) (Slee & David 2015). Here we investigated whether transient plasticity could be reproduced in the IC following passive exposure to sounds with biased statistics and at what time scale this plasticity occurs. To this end we chronically implanted a 16 channel probe in the inferior colliculus (IC) of mice. The electrode can thus be connected to a wireless headstage that can be activated and monitored live without external interference from the experimenter. We passively exposed animals to hours of narrowband clouds of tones at non-traumatic sound levels and measured the subsequent effects on the spectrotemporal characteristics of neurons in the IC across a timescale of seconds, minutes and hours post exposure. These experiments are a proof of concept and serve as a stepping stone towards a better understanding of the underlying 'neural changes surrounding plasticity at subcortical levels. In addition, the directed manipulation of these plastic changes, even outside the developmental period, could yield results which may prove to be of clinical value for hearing rehabilitation strategies.

ACTIVATION OF BASAL FOREBRAIN PARVALBUMIN NEURONS EXERTS FREQUENCY DEPENDENT EFFECTS ON AUDITORY PROCESSING AND BEHAVIOR IN THE RAT.

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Hamid Azimi, Kevin Thomas, Pilar Vaca Sánchez, Michael Harvey, Gregor Rainer
University of Fribourg, Department Of Medicine, Fribourg, Switzerland

The basal forebrain (BF) has been implicated in attention and the modulation of information processing. While the BF provides the main cholinergic input to the cerebral cortex, it also harbors substantial GABAergic populations. Here we study how activation of the GABAergic population in the posterior nucleus basalis (pNB) of the BF impacts auditory pathway activity and behavior. We utilized a PV-Cre rat line to express channel rhodopsin (ChR2) uniquely in PV GABAergic neurons and recorded LFP and single unit activity simultaneously in the pNB, the medial geniculate nucleus (MGN), and the primary auditory cortex (A1). We utilized auditory band-pass noise stimuli covering the 1 kHz to 22 kHz frequency range, which was presented in conjunction with broad-band masking stimulus during the behavioral study. We present evidence for a tonotopic organization of auditory responsive neurons within pNB. Consistent with this, we show that optogenetic activation of pNB PV neurons leads to an increase in the spiking activity of single neurons in both MGN and A1 at their preferred frequency band as well as at adjacent frequency bands, but not distant bands. Detection of a narrow-band target sound in the presence of broad-band noise was compromised during pNB PV activation, consistent with a boosting of neural responses to both target and adjacent masking stimulus. Our findings support the idea that pNB modulation of auditory processing encompasses frequency-specific aspects, permitting precise regulation of sensory inputs rather than the mere enhancement of overall excitability of neurons in the auditory pathway.

AUDITORY TETANIZATION EFFECTS IN HUMAN EVENT-RELATED POTENTIAL (ERP): LONG-TERM POTENTIATION (LTP) AND LATERAL INHIBITION

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Daria Kostanyan[1], Gurgen Soghoyan[2], Daria Kleeva[3], Anna Rebreikina[1], Olga Sysoeva[1]
[1]Sirius University of Science and Technology, Sirius Center For Cognitive Sciences, Sochi, Russian Federation, [2]Skolkovo Institute of Science and Technology, V. Zelman Center For Neurobiology And Brain Restoration, Moscow, Russian Federation, [3]National Research University “Higher School of Economics”, Center For Bioelectric Interfaces, Moscow, Russian Federation

AIM: The plastic changes, resulting from differential exposure to various stimuli, are the basis of learning and memory, that help adapt to a changing environment. Rapid and short-term sensory stimulation/tetanization in humans is proposed to cause long-term potentiation (LTP) like effects similar to those caused by electrical tetanization previously rigorously studied at the cellular level in animals, thus bridging different approaches to learning and memory. METHODS: Twenty-seven participants (11 males, mean age 23.3 ± 5.6) took part in the study with 128-channels EEG registration. Pure tones(1020 Hz, 50ms) were presented every 75ms for 2 minutes(tetanization block). Oddball blocks preceded and followed the tetanization block. This block contained the same stimuli presented as deviant(1020 Hz, probability of 5-10%) interspersed with tones of adjacent frequencies: standard(1000 Hz, 80-90%) and deviant (980 Hz, 5-10%) tones. RESULTS: The N1 component of event-related potential(ERP) was attenuated to non-tetanized tones(both 980 and 1000Hz) over the majority of electrodes after tetanization. This change corresponds with the effect of lateral inhibition that plays a crucial role in the sharpening of the neuronal tuning to increase tone differentiation. Mismatch negativity(MMN) component in response to tetanized tone(1020Hz), while being similar to MMN for non-tetanized tone before tetanization, became larger than that after tetanization, pointing to the increase in its cortical differentiation. CONCLUSIONS: Short-term auditory tetanization changes the cortical representation of tones.

Generalization of sustained neurophysiological effects of short-term auditory 13-Hz stimulation to neighbouring frequency representation in humans.
A fuller understanding of the effects of auditory tetanization in humans would inform better language and sensory learning paradigms; however, there are still unanswered questions. Here, we probe sustained changes in the event-related potentials (ERPs) to 1020- and 980-Hz tones following a rapid presentation of 1020-Hz tone (every 75 ms, 13.3 Hz, tetanization). Consistent with some previous studies, we revealed the increase in the P2 ERP component after tetanization. Contrary to some other studies, we did not observe the expected N1 increase after tetanization even in the identical experimental sequence. We detected a significant N1 decrease after tetanization. Expanding previous research, we showed that P2 increase and N1 decrease are not specific to the stimulus type (tetanized 1020 Hz and non-tetanized 980 Hz), suggesting the generalizability of tetanization effect to the not-stimulated auditory tones, at least to those of the neighbouring frequency. The ERPs' tetanization effects were observed for at least 30 min-the most prolonged interval examined, consistent with the duration of long-term potentiation, LTP. In addition, the tetanization effects were detectable in the blocks where the participants watched muted videos, an experimental setting that can be easily used in children and other challenging groups. Thus, auditory 13-Hz stimulation affects brain processing of tones including those of neighbouring frequencies.

MODULATION OF BRAIN CIRCUITS FOR SENSORY PROCESSING DURING SLEEP STATES

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Ida Luisa Boccalaro, Antoine Adamantidis, Florence Aellen, Thomas Rusterholz, Bozic
University of Bern,, Department Of Neurology, Bern, Switzerland

Sleep is associated with a sensory disconnection from the environment, thought to be mediated by a thalamic gating of sensory-motor processing. Here, we investigated the thalamo-cortical circuit dynamics upon auditory stimulation across sleep states (i.e. wakefulness, NREM, and REM sleep) using single-unit activity and local field potential (LFP) activities recorded from chronically implanted electrodes in the primary auditory cortex (Au1), the central medial thalamus (CMT), the medial geniculate (MG), and hippocampus (HP) in freely-moving wild-type mice. We found similar auditory stimuli-evoked LFP responses during wakefulness and REM sleep whereas their amplitude was significantly higher during NREM sleep. Furthermore, we showed that animals significantly woke up from NREM sleep when the stimuli were delivered on the up phase of CMT slow waves, suggesting a key role for the CMT in mediating sensory-evoked arousals. confirmed by optogenetic silencing and a computational approach. Finally, to test whether the information associated with auditory cues – i.e., danger (conditional stimuli, CS+) versus safety (CS-) – was differentially processed during sleep, we performed an auditory cued fear conditioning followed by re-exposure to CS+ and CS- cues during subsequent sleep. Our results showed an increase in the percentage of awakening from the CS+ after the conditioning, suggesting that the discriminative ability persisted during NREM, but not, REM sleep. Interestingly, the CMT opto-silencing compromises this stimuli discrimination, decreasing the percentage of awakening specifically for the cued-stimuli (CS+). Taken together, our results showed that CMT neurons are central to the processing of environmental auditory cues associated with danger.

CATEGORY LEARNING OF FM SWEEPS IN MICE – BEHAVIORAL STRATEGY AND CORTICAL PLASTICITY

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Or Cotev Yudco, Adi Mizrahi, Ido Maor
The Hebrew university of Jerusalem, Edmond And Lily Safra Center For Neuroscience, Jerusalem, Israel

Background and Methods: To make sense of highly complex environments, the brain uses categorization as a reduction mechanism. Category learning is the process of acquiring these rules of reduction, but the neural mechanisms underlying it are not well understood. Towards this goal, we studied how mice learn categories, and how are those represented in the cortex after learning. Using an automated learning platform, we trained mice to discriminate between two categories - rising frequency modulated (FM) sweeps and falling FM sweeps. We then challenged mice with a rich set of catch trials to decipher what they actually learned as the categorical cue. Next, we performed electrophysiological recording along different stations of the auditory cortex, in expert mice and naïve controls, using the multiarray silicon probe, Neuropixels. **Results:** Mice learned to discriminate efficiently between rising and falling FM sweeps as well as to generalize in response to novel stimuli. Using catch trials we found that mice used the frequency content of the FM sweep as the categorical boundary cue, rather than the slope of the sweep. Preliminary analyses of single neuron data shows increased responses to pure tones representing the category boundary as compared to naive mice, as well as changes in sparseness. **Conclusions**: Mice use the frequency component of sounds to categorize FM sweeps. Category learning is accompanied by plastic changes in the response profile of the single neurons in auditory cortex to sounds as simple as pure tones.

AUDITORY LEARNING DURING ADOLESCENCE

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Benne Praegel, Ido Maor, Adi Mizrahi
The Hebrew university of Jerusalem, Edmond And Lily Safra Center For Neuroscience, Jerusalem, Israel

Aims: Adolescence is known to be a period of uncertainty, exploration, and learning, yet there is little clarity about how even simple forms of learning change with development and are supported by neural circuits that undergo remodeling over the adolescent period. Here, we focused on mice and asked whether auditory learning in a go no-go task differs between adolescent and adult animals. **Methods:** To enable efficient learning of both adult and adolescent groups we trained mice to perform a go no-go task to discriminate among pure tones around a decision boundary of 10khz. We used four stimuli, two easy and two hard Go/No-go sound pairs, separated by 1 octave (easy) and 1/4 octave (hard), respectively. Training was carried out in a behavioral system allowing unrestrained learning environment. **Results:** While expert performance between adolescents and adults was similar, learning curves of adolescent mice were steeper in the easy discrimination pair. In contrast, expert performance of adolescent mice in the hard discrimination pair was inferior compared to adult mice. **Conclusions:** We identify clear differences between adolescent and adult auditory learning, setting the stage for our current electrophysiology study to measure the neural correlates of learning in adolescence compared to adulthood.

TEMPORAL AND RESOLVED HARMONIC PITCH ENCODING IN AUDITORY CORTEX

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Quentin Gaucher, Andrew King, Kerry Walker
University of Oxford, Dept Of Physiology, Anatomy & Genetics, Oxford, United Kingdom

Our perception of the tonal quality of sound is known as "pitch". Pitch is the foundation of musical melody, and plays a key role in human and animal communication. Previous research in ferrets has described neurons which are sensitive to the pitch cues of artificial vowels, which are distributed widely across the auditory cortex (Bizley *et al.*, 2010; Walker *et al.*, 2011), and which correlate with ferrets' trial-to-trial pitch judgments (Bizley *et al.*, 2013). However, these studies did not examine whether the "pitch-sensitive" neurons were able to maintain their tuning to a preferred fundamental frequency (F0) across a variety of stimuli ("pitch-selective" neurons), like those described in the marmoset pitch area (Bendor & Wang, 2005). Here, we investigated the resolved harmonic and temporal periodicity cues that underlie pitch responses in ferret auditory cortex. We recorded the responses of large populations of individual neurons to a variety of sounds that varied in F0 (17 F0 values; 250 - 4000 Hz). Neural responses were measured from ketamine/medetomidine anesthetized adult ferrets using high-channel-count multielectrodes (Neuropixels). We found that auditory cortical neurons often show greater sensitivity to temporal cues than resolved harmonic cues, in keeping with our recent behavioural findings (Walker et al., 2019). We also identified a subset of neurons with pitch-selective responses, similar to those previously reported in marmoset (Bendor & Wang, 2005), suggesting that specialized pitch processing also exists in non-primates.

CORTICAL DEFICIT IN DISCRIMINATION BETWEEN COMMUNICATION SOUNDS IN A MOUSE LACKING TWO-PORE CHANNELS: A CALCIUM IMAGING AND ELECTROPHYSIOLOGICAL STUDY.

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Juliette Royer[1], Anthony Renard[2], Chloé Huetz[1], Jacques Callebert[3], Brice Bathellier[2], Jean-Marc Edeline[1], José-Manuel Cancela[1]
[1]Institut des Neurosciences Paris-Saclay, Université Paris Saclay-cnrs, Saclay, France, [2]Institut Pasteur, INSERM, Institut De L'audition, Paris, France, [3]Hopital Lariboisière, Inserm, Paris, France

Aims: Abnormal integration of sensory stimuli have been suggested to play a role in the altered social behavior of patients with autism spectrum disorder (ASD). This can be explained by altered responses in cortical networks. Here, we explored the role of the lysosomal calcium store in the cortical processing using a mouse deficient in endolysosomal two-pore channels (TPC KO), whose coding chromosomal regions in humans are associated with copy number variation and ASD. Compared with WT mice (C57BL/6), KO mice show deficits in monoamine concentration in temporal cortex. Despite similar audiograms as WT mice, we suspected that the cortical processing of conspecific vocalizations is impaired in KO mice. **Methods**: We investigated the functional role of TPCs in vocalization-induced responses in WT and KO mice in the primary auditory cortex (AI), using in vivo extracellular electrophysiology and two-photon calcium imaging (with GCaMP6s). **Results**: In two-photon calcium imaging, cortical neurons of TPC KO mice were less selective for mouse calls and responded to more categories of vocalization compared to WT mice. Electrophysiological recordings revealed that cortical neurons of TPC KO mice had lower temporal reliability to all communication sounds and showed reduced responses to mouse calls. Calcium imaging and electrophysiological data point out that neurons of TPC KO mice have a lower signal-to-noise ratio and degraded responses to pup calls compared to WT neurons. **Conclusion**: Our results show that, in mice, TPC channels have a functional role in the cortical processing of communication sounds, which could lead to deficits in social behavior.

DEVELOPMENT OF AN AWAKE ANIMAL MODEL FOR HYPERACUSIS SCREENING

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Camille Dejean[1], Typhaine Dupont[2], Noémie Dominique[3], Nicolas Michalski*[4], Sylvie Pucheu[5], Boris Gourévitch[4]
[1]Institut de l'Audition, Pcac, Paris, France, [2]INSERM, Ua06, Paris, France, [3]Institut Pasteur, Integrative Neurobiology Of Cholinergic Systems (cnrs Umr3571), Paris, France, [4]Institut Pasteur, Institut De L'audition, Paris, France, [5]Cilcare, Cilcare, Montpellier, France

For some people, auditory stimulation can be incredibly unpleasant, possibly painful, even at loudness levels considered normal by others. Epidemiological reports suggest that 2% to 15% of people experience a hypersensitivity to everyday sounds, ranging from discomfort to pain, named hyperacusis. This is, by far, the leading form of hypersensitivity to sound and there is currently no treatment for this condition. We still know little about the pathophysiological mechanisms underlying hyperacusis, in particular because we lack reliable animal models, for which the objective quantification of a subjective perception has proved difficult. Hyperacusis and tinnitus are frequently occurring concurrently, which complicates the deciphering of involved mechanisms. To investigate hyperacusis specifically, we thus exposed a cohort of awake mice to an acoustic trauma (2h of noise at 95dB SPL) leading to temporary hearing loss, which is known to induce either tinnitus or hyperacusis or both. Recent studies in animal models have suggested that the neural correlates of hyperacusis would be mediated by enhanced sound-evoked responses and neuronal spiking activities in the auditory cortex, i.e. hyperexcitability, as it is commonly defined. To confirm this hypothesis, we thus tested several behavioural measures as well as electrophysiological measures of the peripheral and cortical neural response to sounds in awake animals before and after trauma. Our goal is to find a combination of neural biomarkers and behavioural changes reliably characterizing the presence of hyperacusis. In particular, whereas auditory thresholds fully recovered after trauma, we observed modifications of the acoustic startle reflex, the behavioural response to sounds.

DEVELOPMENTAL OVEREXPANSION OF CEREBRAL CORTEX IN MICE NEGATIVELY AFFECTS AUDITORY PROCESSING IN ADULTHOOD

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Mirna Merkler[1], Nancy Ip[2], Shuzo Sakata[1]
[1]University of Strathclyde, Strathclyde Institute Of Pharmacy And Biomedical Sciences, Glasgow, United Kingdom, [2]Hong Kong University of Science and Technology, Division Of Life Science, State Key Laboratory Of Molecular Neuroscience And Molecular Neuroscience Center, Hong Kong, China

Cortical size has increased drastically in the course of evolution, and this expansion is thought to be advantageous. However, developmental expansion in cortical size can lead to megalencephaly, frequently found in neurodevelopmental disorders. Changes in the number and ratio of excitatory and inhibitory cortical neurons could lead to abnormal cortical connectivity, ultimately affecting the processing of sensory information. Even though both macrocephaly and atypical sensory processing were found in a high percentage of autism spectrum disorder (ASD) patients, the relationship between the number of cortical neurons and sensory processing is still uncertain. In the present study, we utilized a macrocephalic ASD-like mouse model to investigate how developmental overproduction of superficial cortical excitatory neurons affects auditory processing. We recorded neuronal population activity *in vivo*, simultaneously from the auditory cortex and auditory thalamus, and assessed auditory perception behaviourally. Our treated mice exhibited hyposensitivity to auditory stimuli. Specifically, they had a higher behavioural noise detection threshold, and a reduced spontaneous and auditory-evoked activity of putative excitatory neurons in the auditory cortex. Interestingly, medial geniculate nucleus cells did not show significant changes in activity. Treated mice also showed reduced monosynaptic connectivity within the auditory cortex. Computational modelling confirmed that this weak connectivity can lead to the reduction in excitatory activity. Altogether, our results suggest that an abnormal cortical expansion during development can result in atypical cortical connectivity, negatively affecting auditory cortical processing and behavioural auditory perception in adulthood.

PREDICTIVE CODING OF GLOBAL SEQUENCE VIOLATION IN THE MOUSE AUDITORY CORTEX

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Sara Jamali[1], Stanislas Dehaene[2,3], Timo Van Kerkoerle[2], Brice Bathellier[1]
[1]Institut Pasteur, INSERM, Institut De L'audition, Paris, France, [2]NeuroSpin, Cognitive Neuroimaging Unit, Cea, Inserm, Université Paris-sud, Université Paris-saclay, Gif-sur-Yvette, France, [3]Collège de France, Universite Paris Sciences Lettres, Paris, France

The ability to extract temporal regularities at different time scales in sensory inputs and detect unexpected deviations is a key cognitive ability. The classical auditory oddball paradigm shows that the brain responds to sequence violations at a local time scale, such responses also occur under anesthesia and seem pre-attentive. In contrast, recent studies in humans and monkeys suggest that when the violation concerns regularities over longer time scales, responses to the violation appear only in conscious, attentive subjects. To investigate whether local and global sequence violation responses exist in the mouse, we recorded the auditory cortex using two-photon imaging while mice passively listened to repetitions of 1s-long sequences of five tones. The repeated short sequence contained either a single tone AAAAA or a local violation at its end AAAAB. Purely global violations could be generated by presenting occasionally the AAAAA sequence in a block where AAAAB is repeated. We found that a population of neurons responds to such purely global violations at the end of the AAAAA sequence. This population contained enough information to predict violations on single trials. These global responses were resistant to a wide increase of inter-sequence interval 1.5s - 25s ruling out that short-term adaptation. However, global responses vanished when the difference between A and B sounds is less salient to mice. These results establish that the mouse brain is able to detect global violations in sound sequences in a subgroup of auditory cortex neurons, paving the way for studying circuit mechanisms underlying long-term temporal regularity detection.

TONOTOPY AND POPULATION ACTIVITY CHARACTERISTICS OF AUDITORY CORTICOCOLLICULAR NEURONS

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Kira Andrea, Tatjana Schmitt, Simon Wadle, Jan Hirtz
TU Kaiserslautern, Physiology Of Neuronal Networks, Kaiserslautern, Germany

The auditory cortex (AC) modulates the upstream auditory pathway through descending corticofugal projections. Many of these arise from layer 5 of the AC and terminate in the inferior colliculus. These corticocollicular (CC) connections are involved in processing of complex sounds and auditory related learning. Despite their importance for the auditory system, their population activity patterns remain mainly uninvestigated. We used widefield and 2-photon calcium imaging in awake and anesthetized mice to record the activity of CC neurons after injection of AAV2-retro-GCaMP7f into the inferior colliculus. While widefield imaging revealed a global tonotopic order, local best frequency distribution on single cell level was quite heterogeneous for all AC subfields, yet still more ordered compared to random distributions. This indicates a subtle topographical order of CC neurons. Furthermore, we investigated population activity patterns of CC and surrounding non-CC neurons in response to complex sounds. We found stronger clusters of CC neurons compared to non-CC neurons, which respond more reliable and mostly integrate information over larger distances. This finding supports the idea of the “broadcast” function of L5 CC neurons (see for example: Williamson and Polley. 2019. Parallel pathways for sound processing and functional connectivity among layer 5 and 6 auditory corticofugal neurons. eLife. 8:1-21). Overall, our findings indicate distinct network mechanism of CC neurons in analyzing sound properties.

AUDITORY CORTEX REPRESENTS AN ABSTRACT SENSORIMOTOR RULE

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Samuel Picard[1,2], Yves Weissenberger[2], Samuel Lippl[2,3], Andrew King[2], Johannes Dahmen[2]
[1]University College London, Institute Of Neurology, London, United Kingdom, [2]University of Oxford, Dept Of Physiology, Anatomy & Genetics, Oxford, United Kingdom, [3]Columbia University, Zuckermann Institute, New York, United States of America

Predicting the sensory consequences of one's actions is critical to perception and action in dynamically changing environments. For several established sensorimotor behaviours, such as locomotion and vocalizations, neural correlates of this prediction have been reported throughout sensory cortex. Oftentimes, however, the sensory consequences of an action are abstract, context-dependent, and newly learned, such as when one learns to play an instrument. How does cortex represent such complex sensorimotor rules? To investigate this question, we developed a task in which mice manipulated the frequency of an auditory cursor by licking either of two lick ports, in search for a rewarded target frequency. We then used behavioural manipulations, generalized linear models (GLMs) and two-photon calcium imaging to investigate how violations of this sensorimotor rule are represented in functionally defined auditory cortical regions, beyond purely sensory or movement-related effects. First, behavioural manipulations and GLMs suggest that trained mice monitored the ongoing stream of sounds to adaptively guide their lick behaviour. Second, we find that L2/3 excitatory neurons are sensitive to subtle violations of the sensorimotor rule, even when matching stimulus history and licking. These effects were more pronounced in higher-order subfield A2 than in the primary subfields A1 and AAF. Linear encoding models confirmed that neural responses to rule violations are better explained by sensorimotor prediction errors than by sensory or reward prediction errors. Together, these findings suggest that the relationship between actions and sensory feedback can shape responses along the sensory cortical hierarchy, even when this relationship is abstract and newly learned.

STIMULUS-SPECIFIC ADAPTATION (SSA) IN AUDITORY CORTEX IN AWAKE MICE UNDER 2-PHOTON MICROSCOPY

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Moran Aharoni, Dina Moshitch, Israel Nelken
The Hebrew University of Jerusalem, Edmond And Lily Safra Center For Brain Sciences, Jerusalem, Israel

Stimulus-specific adaptation (SSA) is the response reduction to a common stimulus that does not, or only partially generalize, to other rare stimuli. SSA has been proposed to be a correlate of 'deviance detection', an important computational task of sensory systems. Human Electrophysiological correlates of deviance detection have been studied extensively using various brain potentials. The best known is mismatch negativity (MMN), which peaks ~150–200 ms after the deviant stimulus. SSA is similar, but not identical, to MMN. One difference between SSA in single cells and MMN is their time course. SSA 'rides' on the early cortical responses to sounds, whereas MMN occurs about 100 ms later. Using fiber photometry of calcium signals in the mouse primary auditory cortex, we uncovered large and robust late response components which show deviance sensitivity at ~100-150 ms after stimulus onset. These signals are believed to reflect the average spiking activity of a local network. To search for the single-neuron basis of those late population responses, we used two-photon microscopy to resolve the responses of multiple adjacent neurons. In the anesthetized mouse, we observed population activity that was robust and resembled the late responses components found using fiber photometry. However, single neurons hardly showed auditory responses independent of their surrounding neuropile. We therefore recorded in awake, head-fixed mice. In the awake mouse, we found more single neurons that responded to auditory stimuli independently of the surrounding neuropile. The late responses were however highly variable. We suggest that the reproducible late response components observed in the population activity reflect neuronal ensembles' activity whose membership varies between trials.

AGE-RELATED CHANGES IN THE STRUCTURE OF NEURONS IN THE AUDITORY CORTEX OF RATS

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Jana Svobodova Burianova, Josef Syka
Institute of Experimental Medicine of the Czech Academy of Sciences, Department Of Auditory Neuroscience, Prague, Czech Republic

It has been shown previously that cortical neurons in rats undergo significant morphological age-related changes, e.g. decreasing density of the dendritic tree. However, only few studies described these morphological alterations in the auditory cortex (AC). Here, we aimed to evaluate age-related changes in the Long-Evans rats with the advent of modern morphometric techniques. Using the Golgi-Cox method and Neurolucida software, we analyzed morphology of pyramidal and non-pyramidal neurons in the AC of 3-month-old and 32-month old rats. We did not observe significant changes in the non-pyramidal neurons in any evaluated parameter. In contrast, pyramidal neurons exhibited apparent age-related degradation of the neuronal tree. Their basal dendrites were shorter, occupied less volume, had fewer spines, and had fewer endings. However, the surface of the somata or the length or volume of apical dendrites did not decrease significantly in old animals. These findings demonstrate that non-pyramidal neurons in the AC remain intact in terms of neuronal morphology, while pyramidal neurons show apparent degradation of branching complexity in basal dendrites. This study was supported by the Operational Programme Research, Development and Education in the framework of the project "Centre of Reconstructive Neuroscience", registration number CZ.02.1.01/0.0./0.0/15_003/0000419.

NEURAL CORRELATES OF STREAM FORMATION DURING ACTIVE LISTENING IN THE FERRET AUDITORY CORTEX

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Jules Lebert[1], Carla Griffiths[1], Joseph Sollini[2], Jennifer Bizley[1]
[1]University College London, Ear Institute, London, United Kingdom, [2]University of Nottingham, Faculty Of Medicine & Health Sciences, Nottingham, United Kingdom

Listening in the real world involves making sense of mixtures of multiple overlapping sounds. The brain decomposes such scenes into individual objects, and a sequence of related auditory objects forms a stream. We are investigating the role of the auditory cortex in the formation and maintenance of auditory streams. The temporal coherence theory (Shamma et al., 2011) has provided one explanation for stream formation, postulating that the brain creates a multidimensional representation of sounds along different feature axes, and groups them based on their temporal coherence, to form streams. Supporting this idea, neural correlates of the differences in perception elicited by synchronous and alternating tone have been found in the primary auditory cortex of behaving ferrets (Lu et al., 2017). However, the temporal coherence theory has yet to be tested with more naturalistic sounds composed of multiple streams. To this end, we trained ferrets to detect a target word in a stream of repeating distractor words, spoken by the same talker, played in a background of spatially separated noise (White, pink and speech shaped noise). Neural data were collected in the auditory cortex of behaving ferrets. Neural population level analyses are being implemented to identify correlation structures. We hypothesize that when the animal can successfully segregate noise and speech streams, the neural population will be a uniform structure early in the trial, that will evolve into two distinct correlation structures. Stimulus reconstruction will be performed on the different clusters of neurons to investigate whether they encode for different auditory streams.

MOTOR-RELATED PREDICTIONS IN MOUSE AUDITORY CORTEX ARE CONTEXT-DEPENDENT.

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Alessandro La Chioma, David Schneider
New York University, Center For Neural Science, New York, United States of America

Auditory perception relies on predicting the acoustic consequences of our actions. Correspondingly, neural circuits in the brain respond differently to expected versus unexpected self-generated sounds. In the real world, the same motor action can produce different sounds depending on the environment in which the behavior is produced – e.g. footsteps sound different when walking on concrete compared to fallen leaves. Yet it remains untested whether the brain can dynamically update predictions about self-generated sounds in a context-dependent manner and on an ethological timescale. To address this question, we developed a visual-acoustic virtual reality (VR), in which a head-fixed mouse on a treadmill repeatedly traverses two different environments, each consisting of a distinct visual corridor accompanied by distinct artificial footstep sounds. Following extensive behavioral acclimation, we made high-density neuronal recordings from auditory cortex as mice traversed VR and experienced either expected or deviant footsteps. We observe overall strong suppression of neural responses to self-generated sounds compared to the same sounds heard passively. When mice hear footstep sounds in the wrong visual context, neural responses are on average larger than when mice hear footstep sounds in the correct context, consistent with an expectation violation. Expectation violations emerge almost immediately after a mouse enters a new context, suggesting a rapid updating of predictions in parallel with behavior. Neurons with strong context-dependent modulation tend to reside in infragranular cortex. Together, our results suggest that the auditory cortex may combine auditory and motor signals with visual spatial cues for real-time, context-dependent processing of self-generated sounds.

Disparity Sensitivity and Binocular Integration in Mouse Visual Cortex Areas.
Binocular disparity, the difference between the two eyes' images, is a powerful cue to generate the 3D depth percept known as stereopsis. In primates, binocular disparity is processed in multiple areas of the visual cortex, with distinct contributions of higher areas to specific aspects of depth perception. Mice, too, can perceive stereoscopic depth, and neurons in primary visual cortex (V1) and higher-order, lateromedial (LM) and rostrolateral (RL) areas were found to be sensitive to binocular disparity. A detailed characterization of disparity tuning across mouse visual areas is lacking, however, and acquiring such data might help clarifying the role of higher areas for disparity processing and establishing putative functional correspondences to primate areas. We used two-photon calcium imaging in female mice to characterize the disparity tuning properties of neurons in visual areas V1, LM, and RL in response to dichoptically presented binocular gratings, as well as random dot correlograms (RDC). In all three areas, many neurons were tuned to disparity, showing strong response facilitation or suppression at optimal or null disparity, respectively, even in neurons classified as monocular by conventional ocular dominance (OD) measurements. Neurons in higher areas exhibited broader and more asymmetric disparity tuning curves compared with V1, as observed in primate visual cortex. Finally, we probed neurons' sensitivity to true stereo correspondence by comparing responses to correlated RDC (cRDC) and anticorrelated RDC (aRDC). Area LM, akin to primate ventral visual stream areas, showed higher selectivity for correlated stimuli and reduced anticorrelated responses, indicating higher-level disparity processing in LM compared with V1 and RL. A major cue for inferring 3D depth is disparity between the two eyes' images. Investigating how binocular disparity is processed in the mouse visual system will not only help delineating the role of mouse higher areas for visual processing, but also shed light on how the mammalian brain computes stereopsis. We found that binocular integration is a prominent feature of mouse visual cortex, as many neurons are

selectively and strongly modulated by binocular disparity. Comparison of responses to correlated and anticorrelated random dot correlograms (RDC) revealed that lateromedial area (LM) is more selective to correlated stimuli, while less sensitive to anticorrelated stimuli compared with primary visual cortex (V1) and rostrolateral area (RL), suggesting higher-level disparity processing in LM, resembling primate ventral visual stream areas.

Area-Specific Mapping of Binocular Disparity across Mouse Visual Cortex.
Depth perception is a fundamental feature of many visual systems across species. It is relevant for crucial behaviors, like spatial orientation, prey capture, and predator detection. Binocular disparity, the difference between left and right eye images, is a powerful cue for depth perception, as it depends on an object's distance from the observer [1,2]. In primates, neurons sensitive to binocular disparity are found throughout most of the visual cortex, with distinct disparity tuning properties across primary and higher visual areas, suggesting specific roles of different higher areas for depth perception [1-3]. Mouse primary visual cortex (V1) has been shown to contain disparity-tuned neurons, similar to those found in other mammals [4,5], but it is unknown how binocular disparity is processed beyond V1 and whether it is differentially represented in higher areas. Beyond V1, higher-order, lateromedial (LM) and rostrolateral (RL) areas contain the largest representation of the binocular visual field [6,7], making them candidate areas for investigating downstream processing of binocular disparity in mouse visual cortex. In turn, comparison of disparity tuning across different mouse visual areas might help delineating their functional specializations, which are not well understood. We find clear differences in neurons' preferred disparities across areas, suggesting that higher visual area RL is specialized for encoding visual stimuli very close to the mouse. Moreover, disparity preference is related to visual field elevation, likely reflecting an adaptation to natural image statistics. Our results reveal ethologically relevant areal specializations for binocular disparity processing across mouse visual cortex.

DISTINCT NEUROPHYSIOLOGICAL RESPONSE MECHANISMS FOR NON-VERBAL AND VERBAL STIMULI IN AGE RELATED HEARING LOSS: A P300 STUDY

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Tatiana Marques[1], João Castelhano[1], Catarina Duarte[1], Inês Batista[2], João Rodrigues[2], Carla Moura[3], António Miguéis[4], Miguel Castelo-Branco[5]
[1]Coimbra Institute for Biomedical Imaging and Translational Research, Coimbra Institute For Biomedical Imaging And Translational Research, Coimbra, Portugal, [2]Coimbra Health School, Polytechnic Institute of Coimbra, Coimbra, Portugal, Audiology, Physiotherapy And Environmental Health Department, Coimbra, Portugal, [3]University of Porto, Faculty of Medicine, Porto, Portugal, Department Of Genetics, Portugal, Portugal, [4]University of Coimbra, Coimbra, Portugal, Otorhinolaryngology, Coimbra, Portugal, [5]University of Coimbra, Cibit - Coimbra Institute For Biomedical Imaging And Translational Research, Coimbra, Portugal

Aims: Physiological mechanisms underlying the brain changes and the mechanistic basis of the association between age-related hearing loss (ARHL) and poorer speech performance remain unknown. We investigated the effects of non-verbal and verbal stimuli on the cognitive processing of auditory stimuli using a P300 paradigm in older adults. **Methods:** Sixteen older-adults with no history of neuropsychiatric disorders, or previous use of hearing aids were divided into hearing loss (HL) and normal hearing listeners (NHL) groups. HL was determined by pure tone average (PTA) thresholds at 0.5, 1, 2 and 4 kHz. PTAs ≥ 25 dB defined HL. P300 was recorded using non-verbal and verbal stimuli. For the speech stimuli, the /ba/ and /ta/ were the standard and deviant stimuli, respectively. The non-verbal paradigm comprised 1kHz/2kHz as standard/deviant stimuli. **Results**: PTA of the right ear was 35.94 dB and 17.50, in HL and NHL groups, and of left ear was 39.53 dB and 18.28 dB, respectively. Significant physiological changes were observed in the HL group, specifically a reduction in P300 amplitude with consonant-vowel stimuli compared with non-verbal stimuli, while a decrease in P300 latency was observed exclusively with verbal sounds. Similarly, in NHL group a peak amplitude pattern was observed, however both amplitude and latency increased, unlike hearing-impaired participants. **Conclusions:** Results support the idea that ARHL may differentially impact neural encoding of verbal auditory cues, providing evidence that auditory cortical processing is impaired due to ARHL. Furthermore, changes in P300 may play a valuable role as a brain-based biomarker for ARHL.

CORTICAL ADAPTATION TO SOUND REVERBERATION

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Andrew King, Aleksandar Ivanov, Benjamin Willmore, Kerry Walker, Nicol Harper
University of Oxford, Dept Of Physiology, Anatomy & Genetics, Oxford, United Kingdom

In almost every natural environment, sounds are reflected by nearby objects, producing many delayed and distorted copies of the original sound, known as reverberation. Our brains usually cope well with reverberation, allowing us to recognize sound sources regardless of their environments. In contrast, reverberation can cause severe difficulties for speech recognition algorithms and hearing-impaired people. The present study examines how the auditory system copes with reverberation. We trained a linear model to recover a rich set of natural, anechoic sounds from their simulated reverberant counterparts. The model neurons achieved this by extending the inhibitory component of their receptive filters for more reverberant spaces, and did so in a frequency-dependent manner. These predicted effects were observed in the responses of auditory cortical neurons of ferrets in the same simulated reverberant environments. Together, these results suggest that auditory cortical neurons adapt to reverberation by adjusting their filtering properties in a manner consistent with dereverberation.

ALTERED SENSORY GATING IN PERSONS WITH TINNITUS IN RESPONSE TO REGULAR AND IRREGULAR AUDITORY ODDBALL SEQUENCES

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Pia Brinkmann[1], Jana Devos[2,3], Jelle Van Der Eerden[4], Jasper Smit[3,5], Sonja Kotz[1], Marcus Janssen[3,6], Michael Schwartze[1]
[1]Maastricht University, Faculty Of Psychology And Neuroscience, Maastricht, Netherlands, [2]Maastricht University Medical Center, Department Of Ear, Nose, Throat, Head And Neck Surgery, Maastricht, Netherlands, [3]Maastricht University, School For Mental Health And Neuroscience, Maastricht, Netherlands, [4]Technical University Eindhoven, Department Of Medical Engineering, Eindhoven, Netherlands, [5]Zuyderland Medical Center, Department Of Ear, Nose, Throat, Head And Neck Surgery, Heerlen, Netherlands, [6]Maastricht University Medical Center, Department Of Clinical Neurophysiology, Maastricht, Netherlands

Aims: Maladaptive sensory gating (i.e., filtering-out irrelevant information) at the level of the thalamus is thought to be an underlying mechanism in persons with tinnitus. This mechanism can be detected by reduced suppression of P50 and N100 in response to (paired) repetitive auditory stimuli. Sensory gating is assumed to be influenced by temporal manipulation of auditory sequences. Therefore, the goal of the current study is to assess this process in persons with and without tinnitus using EEG. **Methods**: Modulations of P50 and N100 amplitudes were assessed in two oddball sequences in persons with tinnitus (n=25) and a control group (n=25) matched for age, sex, and hearing loss. We used a temporally regular sequence consisting of paired sinusoidal tones (standard, deviant) with fixed short (200 ms) intra-stimulus and long (700 ms) inter-stimulus intervals. In the temporally irregular sequence, the intra- and inter-stimulus intervals varied randomly between 100-300 ms and 350-1050 ms, respectively. **Results**: Preliminary data of ten participants suggest a trend toward altered sensory gating in persons with tinnitus as compared to controls. Specifically, the commonly found amplitude suppression of the P50 and N100 event-related potentials appears reduced in persons with tinnitus. **Conclusions**: The current findings enhance our understanding of the neurocognitive signatures underlying tinnitus. Maladaptive sensory gating might indicate dysfunctional central inhibition, suggesting modified sub-cortical network functioning. These results may eventually facilitate the development of new, targeted interventions.

Cerebellar Activation During Simple and Complex Bimanual Coordination: an Activation Likelihood Estimation (ALE) Meta-analysis.
Bimanual coordination is an important part of everyday life and recruits a large neural network, including the cerebellum. The specific role of the cerebellum in bimanual coordination has not yet been studied in depth, although several studies indicate a differential role of the anterior and posterior cerebellum depending on the complexity of the coordination. An activation likelihood estimation (ALE) meta-analysis was used combining the data of several functional MRI studies involving bimanual coordination tasks with varying complexities to unravel the involvement of the different areas of the cerebellum in simple and complex bimanual coordination. This study confirms the general bimanual network as found by Puttemans et al. (Puttemans et al. in J Neurosci 25:4270-4278, 2005) and highlights the differences between preferred in-phase (simultaneous movements of homologous muscle groups) and anti-phase movement conditions (alternating movements of homologous muscle groups), and more complex, non-preferred bimanual movements (e.g., out-of-phase movements). Our results show a differential role for the anterior and posterior vermis in bimanual coordination, with a role for the anterior vermis in anti-phase and complex bimanual coordination, and an exclusive role for the posterior vermis in complex bimanual movements. In addition, the way complexity was manipulated also seems to play a role in the involvement of the anterior and posterior vermis. We hypothesize that the anterior vermis is involved in sequential/spatial control, while the posterior vermis is involved in temporal control of (bimanual) coordination, though other factors such as (visual) feedback and continuity of the movement also seem to have an impact. More studies are needed to unravel the specific role of the cerebellar vermis in bimanual coordination.

About time: Ageing influences neural markers of temporal predictability.
Timing abilities help organizing the temporal structure of events but are known to change systematically with age. Yet, how the neuronal signature of temporal predictability changes across the age span remains unclear. Younger (n = 21; 23.1 years) and older adults (n = 21; 68.5 years) performed an auditory oddball task, consisting of isochronous and random sound sequences. Results confirm an altered P50 response in the older compared to younger participants. P50 amplitudes differed between the isochronous and random temporal structures in younger, and for P200 in the older group. These results suggest less efficient sensory gating in older adults in both isochronous and random auditory sequences. N100 amplitudes were more negative for deviant tones. P300 amplitudes were parietally enhanced in younger, but not in older adults. In younger participants, the P50 results confirm that this component marks temporal predictability, indicating sensitive gating of temporally regular sound sequences.

Auditory thalamus dysfunction and pathophysiology in tinnitus: a predictive network hypothesis.
Tinnitus is the perception of a 'ringing' sound without an acoustic source. It is generally accepted that tinnitus develops after peripheral hearing loss and is associated with altered auditory processing. The thalamus is a crucial relay in the underlying pathways that actively shapes processing of auditory signals before the respective information reaches the cerebral cortex. Here, we review animal and human evidence to define thalamic function in tinnitus. Overall increased spontaneous firing patterns and altered coherence between the thalamic medial geniculate body (MGB) and auditory cortices is observed in animal models of tinnitus. It is likely that the functional connectivity between the MGB and primary and secondary auditory cortices is reduced in humans. Conversely, there are indications for increased connectivity between the MGB and several areas in the cingulate cortex and posterior cerebellar regions, as well as variability in connectivity between the MGB and frontal areas regarding laterality and orientation in the inferior, medial and superior frontal gyrus. We suggest that these changes affect adaptive sensory gating of temporal and spectral sound features along the auditory pathway, reflecting dysfunction in an extensive thalamo-cortical network implicated in predictive temporal adaptation to the auditory environment. Modulation of temporal characteristics of input signals might hence factor into a thalamo-cortical dysrhythmia profile of tinnitus, but could ultimately also establish new directions for treatment options for persons with tinnitus.

DEVELOPMENT OF HEMISPHERIC SPECIALIZATIONS: DIFFERENCES IN THE MATURATION OF THE LEFT AND RIGHT AUDITORY CORTEX

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Demetrios Neophytou[1], Ashlan Reid[2], Hysell Oviedo[1,2]
[1]CUNY Graduate Center, Biology, New York, United States of America, [2]City College of New York, Biology, New York, United States of America

From humans to mice, the task of decoding vocalizations is divided into distinct computational functions in the left and right Auditory Cortices. A gap in current knowledge is how auditory cortical circuits develop specializations to subserve these lateralized functions. One possible mechanism that could lead to the emergence of specializations is differences in the timing of critical periods. Previous studies have identified the maturation of GABAergic tone as a key event in the onset and closure of the critical period, in particular parvalbumin positive (PV) interneurons. We compared the density of PV interneurons and their ensheathment by perineuronal nets before, during, and after the critical period (p10-p20), and found that the right ACx was consistently ahead of the left ACx in GABAergic development. This difference was also reflected in synaptic function: the right ACx had a higher frequency of spontaneous inhibitory postsynaptic currents. The appearance of myelin in cortex also marks the end of critical periods, and we found a faster rate of myelination in the right ACx. Differences were also found in glutamatergic signaling: we found higher intensity of the thalamocortical vesicular glutamate transporter (VGluT2) in the right ACx throughout the critical period. Finally, using cfos we found that the maturation of sound-evoked responses was also lateralized: the right ACx was preferentially responsive to frequency sweeps earlier than the left ACx was preferentially responsive to vocalizations. Our results suggest that the left ACx remains plastic longer to allow the development of specializations involved in vocalization processing.

Using Neural Circuit Interrogation in Rodents to Unravel Human Speech Decoding.
The neural circuits responsible for social communication are among the least understood in the brain. Human studies have made great progress in advancing our understanding of the global computations required for processing speech, and animal models offer the opportunity to discover evolutionarily conserved mechanisms for decoding these signals. In this review article, we describe some of the most well-established speech decoding computations from human studies and describe animal research designed to reveal potential circuit mechanisms underlying these processes. Human and animal brains must perform the challenging tasks of rapidly recognizing, categorizing, and assigning communicative importance to sounds in a noisy environment. The instructions to these functions are found in the precise connections neurons make with one another. Therefore, identifying circuit-motifs in the auditory cortices and linking them to communicative functions is pivotal. We review recent advances in human recordings that have revealed the most basic unit of speech decoded by neurons is a phoneme, and consider circuit-mapping studies in rodents that have shown potential connectivity schemes to achieve this. Finally, we discuss other potentially important processing features in humans like lateralization, sensitivity to fine temporal features, and hierarchical processing. The goal is for animal studies to investigate neurophysiological and anatomical pathways responsible for establishing behavioral phenotypes that are shared between humans and animals. This can be accomplished by establishing cell types, connectivity patterns, genetic pathways and critical periods that are relevant in the development and function of social communication.

HOW EMOTIONAL STATES SHAPE PERCEPTION: A MECHANISTIC UNDERSTANDING OF STATE DEPENDENT AUDITORY PROCESSING

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Ghattas Bisharat, Jennifer Resnik
Ben-Gurion University, Life Sciences, Beer Sheva, Israel

Our perception varies depending on our emotional state, adjusting our behavioral response to the same stimulus under different circumstances. These perceptual adaptations are especially extreme in aversive emotional states, such as chronic stress, that can threaten our survival. Stressful states frequently modify various features of sensory perception, such as reducing response thresholds and increasing sensitivity. In many cases, these perceptual adaptations increase our chances of evolutionary survival, helping us overcome dangerous situations; in other cases, they can exacerbate or even trigger mental disorders or sensory, such as PTSD or tinnitus. Although we have made tremendous progress in studying the central stress response system and its effect on learning and memory, **we do not yet possess a mechanistic understanding of how stressful states shape our perception.** *How is emotional state-information represented in our sensory systems? How do changes in emotional state shape perception?* To tackle this question, we developed a rodent auditory behavioral approach that enables direct evaluation of perception. We coupled these behavioral paradigms to manipulations of the animal's emotional state and, using two-photon calcium imaging, detailed probing of neural activity modulations at the network and cell-specific levels in the auditory cortex. Our findings indicate that stress modulates differently spontaneous and tone evoked activity of inhibitory and excitatory cells. Moreover, we found changes in perception as a result of stress induced changes to cortical activity. Our findings could have clinical implications by explaining how stressful states distort the neural representation of sensory stimuli and alter our perception of the world.

LEARNING TRAJECTORY PREDICTS THE LEVEL OF RECRUITMENT OF A PRIMARY SENSORY CORTEX IN A NEGATIVE REINFORCEMENT BEHAVIORAL PARADIGM

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Anthony Lourdiane, Laurent Bourdieu, Jean-François Léger
Institut de Biologie de l'Ecole Normale Superieure, Cortical Dynamics And Coding Mechanisms, Paris, France

It is thought that learning to associate sensory stimulus and action induces shifts in sensory representations towards the learned stimuli. This was observed in numerous studies, multiple brain areas, including the auditory cortex (A1). In the latter, the resulting modifications are believed to reflect plastic changes that prepare the brain to better perceive relevant sensory cues. However, other efficient auditory pathways coexist, and precise optogenetic inactivation of A1 has shown that A1 is not even required for some simple sound-action associations. Even when A1 remains active, recent chronic imaging studies have revealed a somewhat less consensual view of learning-induced changes in A1, failing to demonstrate permanent changes in the selectivity of individual neurons after training. What determines the presence or absence of learning-related plasticity in A1 during a sound-action association? Recent high-throughput behavioral approaches have tested among large cohorts the role of task difficulty in A1 plasticity recruitment. But no clear relationship has been found between average A1 change and behavioral performance. Here, using the statistical power of chronic two-photon imaging of large neuronal assemblies in mice, we examine the possibility that the difficulty of a task, as experienced by each mouse, may *individually* determine the extent of A1-plasticity induced. We found a clear parallel between the learning trajectories of individual mice and the *permanent* change of sound representation in A1, as measured in a task-irrelevant context. Our results reconcile the heterogeneous observations that learning sound-action associations can have diverse consequences for A1 selectivity remodeling.

DIFFERENCES IN AUDITORY TEMPORAL PROCESSING IN THE LEFT AND RIGHT AUDITORY CORTICES OF THE RAT

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Kateryna Pysanenko[1], Zbyněk Bureš[1,2], Josef Syka[1]
[1]Institute of Experimental Medicine CAS, Department Of Auditory Neuroscience, Prague, Czech Republic, [2]Czech Institute of Informatics, Robotics and Cybernetics, Czech Technical University, Department Of Cognitive Systems And Neurosciences, Prague, Czech Republic

Aims In the present study, we examined the hemispheric differences in central auditory processing of temporally structured stimuli in the adult rats. **Methods** Evoked neuronal responses to temporally structured stimuli (sinusoidally frequency modulated [FM] tones, frequency sweeps, amplitude modulated [AM] tones and noise, click trains with constant and variable inter-click intervals) and natural vocalization were recorded from the left (LAC) and right (RAC) auditory cortices in adult (4–6 months old) anaesthetized F344 rats. Using vector strength, modulation-transfer functions, van Rossum distances, and direction-selectivity index (DSI), synchronization with stimulus structure and response reliability were compared in the LAC and the RAC. **Results** The RAC exhibits a higher synchronization ability for all periodic stimuli except AM tones. Reproducibility of responses to periodic stimuli was also better in the RAC. On the other hand, the LAC mostly shows higher relative response magnitudes to temporally structured stimuli. The responses to vocalizations were similar in both hemispheres, however, the RAC exhibited a higher response to the onset of the second bout. The proportion of direction-selective neurons was higher in the RAC. **Conclusions** The results show that coding of temporally structured stimuli in the RAC is based more on the temporal code, while the LAC is more focused on the rate code. Direction selectivity is more developed in the RAC. These results confirm and extend our previous findings obtained both electrophysiologically and behaviorally. This work is supported by the project INTER-ACTION LTAIN 19201.

The influence of developmental noise exposure on the temporal processing of acoustical signals in the auditory cortex of rats.
Previous experiments have acknowledged that inappropriate or missing auditory inputs during the critical period of development cause permanent changes of the structure and function of the auditory system (Bures et al., 2017). We explore in this study how developmental noise exposure influences the coding of temporally structured stimuli in the neurons of the primary auditory cortex (AC) in Long Evans rats. The animals were exposed on postnatal day 14 (P14) for 12 minutes to a loud (125 dB SPL) broad-band noise. The responses to an amplitude-modulated (AM) noise, frequency-modulated (FM) tones, and click trains, were recorded from the right AC of rats of two age groups: young-adult (ca. 6 months old) and adult (ca. 2 years old), both in the exposed animals and in control unexposed rats. The neonatal exposure resulted in a higher synchronization ability (phase-locking) of the AC neurons for all three stimuli; furthermore, the similarity of neuronal response patterns to repetitive stimulation was higher in the exposed rats. On the other hand, the exposed animals showed a steeper decline of modulation-transfer functions towards higher modulation frequencies/repetition rates. Differences between the two age groups were also apparent; in general, aging had qualitatively the same effect as the developmental exposure. The current results demonstrate that brief noise exposure during the maturation of the auditory system influences both the temporal and the rate coding of periodically modulated sounds in the AC of rats; the changes are permanent and observable up to late adulthood.

Acoustically Enriched Environment during the Critical Period of Postnatal Development Positively Modulates Gap Detection and Frequency Discrimination Abilities in Adult Rats.
Throughout life, sensory systems adapt to the sensory environment to provide optimal responses to relevant tasks. In the case of a developing system, sensory inputs induce changes that are permanent and detectable up to adulthood. Previously, we have shown that rearing rat pups in a complex acoustic environment (spectrally and temporally modulated sound) from postnatal day 14 (P14) to P28 permanently improves the response characteristics of neurons in the inferior colliculus and

auditory cortex, influencing tonotopical arrangement, response thresholds and strength, and frequency selectivity, along with stochasticity and the reproducibility of neuronal spiking patterns. In this study, we used a set of behavioral tests based on a recording of the acoustic startle response (ASR) and its prepulse inhibition (PPI), with the aim to extend the evidence of the persistent beneficial effects of the developmental acoustical enrichment. The enriched animals were generally not more sensitive to startling sounds, and also, their PPI of ASR, induced by noise or pure tone pulses, was comparable to the controls. They did, however, exhibit a more pronounced PPI when the prepulse stimulus was represented either by a change in the frequency of a background tone or by a silent gap in background noise. The differences in the PPI of ASR between the enriched and control animals were significant at lower (55 dB SPL), but not at higher (65-75 dB SPL), intensities of background sound. Thus, rearing pups in the acoustically enriched environment led to an improvement of the frequency resolution and gap detection ability under more difficult testing conditions, i.e., with a worsened stimulus clarity. We confirmed, using behavioral tests, that an acoustically enriched environment during the critical period of development influences the frequency and temporal processing in the auditory system, and these changes persist until adulthood.

Age-related changes in the temporal processing of acoustical signals in the auditory cortex of rats.

Age-related hearing loss is manifested primarily by a decreased sensitivity to faint sounds, that is, by elevation of the hearing thresholds. Nevertheless, aging also affects the ability of the auditory system to process temporal parameters of the sound stimulus. To explore the precision and reliability of auditory temporal processing during aging, responses to several types of sound stimuli were recorded from neurons of the auditory cortex (AC) of young and aged anaesthetized Fischer 344 rats. In response to broad-band noise bursts, the aged rats exhibited larger response magnitudes, a higher proportion of monotonic units, and also a larger variability of response magnitudes, suggesting a lower stability of the rate code. Of primary interest were the responses to temporally structured stimuli (amplitude-modulated (AM) noise, frequency-modulated (FM) tones, and click trains) recorded separately in the right and left AC. Significant differences of temporal processing were already found between the neuronal responses in the left and right AC in the young animals: for the click trains, the left hemisphere exhibited a greater responsiveness to higher repetition rates, lower vector strength values, and a lower similarity of responses. The two hemispheres were also affected differently by aging. In the right hemisphere, neurons in the aged animals displayed worse synchronization with the AM noise and clicks, but better synchronization with the FM tone. In the left hemisphere, neuronal synchronization with the stimulus modulation improved at a higher age for all three stimuli. The results show that the ability of the aging auditory system to process temporal parameters of the stimulus strongly depends on the stimulus type and on laterality. Furthermore, the commonly reported age-related decline in the temporal processing ability cannot be regarded as general as, at least at the neuronal level in the AC, objective measures of the temporal representation often exhibit age-related improvement instead of deterioration.

Neurod1 Is Essential for the Primary Tonotopic Organization and Related Auditory Information Processing in the Midbrain.

Hearing depends on extracting frequency, intensity, and temporal properties from sound to generate an auditory map for acoustical signal processing. How physiology intersects with molecular specification to fine tune the developing properties of the auditory system that enable these aspects remains unclear. We made a novel conditional deletion model that eliminates the transcription factor NEUROD1 exclusively in the ear. These mice (both sexes) develop a truncated frequency range with no neuroanatomically recognizable mapping of spiral ganglion neurons onto distinct locations in the cochlea nor a cochleotopic map presenting topographically discrete projections to the cochlear nuclei. The disorganized primary cochleotopic map alters tuning properties of the inferior colliculus units, which display abnormal frequency, intensity, and temporal sound coding. At the behavioral level, animals show alterations in the acoustic startle response, consistent with altered neuroanatomical and physiological properties. We demonstrate that absence of the primary afferent topology during embryonic development leads to dysfunctional tonotopy of the auditory system. Such effects have never been investigated in other sensory systems because of the lack of comparable single gene mutation models. All sensory systems form a topographical map of neuronal projections from peripheral sensory organs to the brain. Neuronal projections in the auditory pathway are cochleotopically organized, providing a tonotopic map of sound frequencies. Primary sensory maps typically arise by molecular cues, requiring physiological refinements. Past work has demonstrated physiologic plasticity in many senses without ever molecularly undoing the specific mapping of an entire primary sensory projection. We genetically manipulated primary auditory neurons to generate a scrambled cochleotopic projection. Eliminating tonotopic representation to auditory nuclei demonstrates the inability of physiological processes to restore a tonotopic presentation of sound in the midbrain. Our data provide the first insights into the limits of physiology-mediated brainstem plasticity during the development of the auditory system.

Fast tonotopy mapping of the rat auditory cortex with a custom-made electrode array.
We present a custom-made multielectrode array for the recording of evoked potentials during acute experiments in rats, which offers a quick and reliable estimation of the cortical tonotopy. The array consists of electrodes represented by insulated copper wires of 0.09 mm diameter fixed in epoxy resin in a 3 x 5 arrangement, with final impedances of 410-800 kOhm. The array was placed on the brain surface of anesthetized rats approximately at the location of the auditory cortex (AC) and the cortical evoked potentials (middle-latency responses, MLR) were elicited by a series of tone pips of different frequencies at 50 dB of sound pressure level (SPL) intensity. The frequency that evoked the highest MLR amplitude (best frequency, BF) was identified for each electrode. The obtained distribution of the BFs characterized the cortical tonotopy, and it correlated with the frequency selectivity of neurons recorded at the same positions by an extracellular microelectrode. Although the space resolution of the array did not allow for the identification of AC sub regions, the array proved to be a reliable tool for a quick estimation and prediction of areas of interest for the subsequent measurements of neurons by more precise techniques.

Acoustical Enrichment during Early Development Improves Response Reliability in the Adult Auditory Cortex of the Rat.
It is well known that auditory experience during early development shapes response properties of auditory cortex (AC) neurons, influencing, for example, tonotopical arrangement, response thresholds and strength, or frequency selectivity. Here, we show that rearing rat pups in a complex acoustically enriched environment leads to an increased reliability of responses of AC neurons, affecting both the rate and the temporal codes. For a repetitive stimulus, the neurons exhibit a lower spike count variance, indicating a more stable rate coding. At the level of individual spikes, the discharge patterns of individual neurons show a higher degree of similarity across stimulus repetitions. Furthermore, the neurons follow more precisely the temporal course of the stimulus, as manifested by improved phase-locking to temporally modulated sounds. The changes are persistent and present up to adulthood. The results document that besides basic alterations of receptive fields presented in our previous study, the acoustic environment during the critical period of postnatal development also leads to a decreased stochasticity and a higher reproducibility of neuronal spiking patterns.

The Effect of Complex Acoustic Environment during Early Development on the Responses of Auditory Cortex Neurons in Rats.
Acoustical environment plays an important role during the maturation of the auditory system. It has been shown that the sensory inputs to the developing centres influence the development of the structure of projections, neuronal responsiveness, excitatory-inhibitory balance, or tonotopical arrangement, throughout the auditory pathway. Our previous study (Bures et al., 2014) showed that rats reared in a complex acoustic environment (spectrally and temporally modulated sound reinforced by an active behavioural paradigm with a positive feedback) exhibit permanently improved response characteristics of the inferior colliculus (IC) neurons. Extending these results, the current work provides evidence that the changes occur also at the level of auditory cortex (AC). In particular, the enriched animals have lower excitatory thresholds, sharper frequency selectivity, and a lower proportion of non-monotonic rate-intensity functions. In contrast to the changes observed in the IC, the cortical neurons of enriched animals have lower response magnitudes. In addition, the enrichment changed the AC responsiveness to frequency-modulated and also to a lesser extent, amplitude-modulated stimuli. Significantly, the alterations span the entire hearing range and may be regarded as general and not directly linked to the characteristics of the acoustical stimulation. Furthermore, these developmentally induced changes are permanent and detectable in adulthood. The findings indicate that an acoustically enriched environment during the critical period of postnatal development influences basic properties of neuronal receptive fields in the AC, which may have implications for the ability to detect and discriminate sounds.

Cooling of the auditory cortex modifies neuronal activity in the inferior colliculus in rats.
There are powerful pathways descending from the auditory cortex (AC) to the inferior colliculus (IC), yet their function is not fully understood. The aim of this study is to examine the effects of a reversible cortical inactivation, achieved by cooling of the AC, on the responses of neurons in the rat IC. Extracellular single-unit or multi-unit activity was recorded in the IC of anaesthetized rats with a 16-channel multielectrode probe introduced along the IC dorso-ventral axis through the dorsal cortex (DCIC) to the central nucleus of the IC (CIC). Cooling of the AC produced an increase in spontaneous activity and magnitude of the sound-evoked response in 47% of the IC neurons. Maximal changes in the neuronal activity were observed in the DCIC and the central part of the CIC. The final segments of the sustained responses to 60 ms stimuli and the off responses were more affected than the onset segments. Inactivation of the AC resulted in a suppression of the post-

excitatory inhibition and neuronal adaptation, which was reflected in a pronounced enhancement of synchronized responses to a series of fast repeated clicks. The response parameters recovered, at least partly, to the pre-cooling levels 1 h after the cooling cessation. The frequency tuning properties of the IC neurons did not show any significant changes during the cooling period. The results demonstrate that AC cooling inactivates excitatory corticofugal pathways and results in a less activated intrinsic inhibitory network in the IC.

Differential distribution of glycine receptor subtypes at the rat calyx of Held synapse.
The properties of glycine receptors (GlyRs) depend upon their subunit composition. While the prevalent adult forms of GlyRs are heteromers, previous reports suggested functional α homomeric receptors in mature nervous tissues. Here we show two functionally different GlyRs populations in the rat medial nucleus of trapezoid body (MNTB). Postsynaptic receptors formed α1/β-containing clusters on somatodendritic domains of MNTB principal neurons, colocalizing with glycinergic nerve endings to mediate fast, phasic IPSCs. In contrast, presynaptic receptors on glutamatergic calyx of Held terminals were composed of dispersed, homomeric α1 receptors. Interestingly, the parent cell bodies of the calyces of Held, the globular bushy cells of the cochlear nucleus, expressed somatodendritic receptors (α1/β heteromers) and showed similar clustering and pharmacological profile as GlyRs on MNTB principal cells. These results suggest that specific targeting of GlyR β-subunit produces segregation of GlyR subtypes involved in two different mechanisms of modulation of synaptic strength.

A cortical lateralization is a functional organization observed in most sensory modalities and in most evolved species. In the auditory domain, the cerebral lateralization is devolved to spatial hearing, with each hemisphere primarily involved in processing the localization of sound in contralateral space. The representation of the contralateral auditory field is underpinned by contralateral aural dominance which results from complex neural interactions between inputs from each ear. We recently showed (Vannson et al 2020) that unilateral hearing loss induces deficits in binaural integration (spatial localization and speech understanding in noise) but also reverses contralateral aural dominance in favor of the preserved ipsilateral ear. The extent of this brain reorganization is directly correlated to the extent of the behavioral deficit in sound localization. A second study in a group of subjects with asymmetric hearing loss treated with a cochlear implant demonstrated that restoration of auditory inputs to the deaf ear through electrical stimulation restored contralateral hemispheric dominance of both the better and impaired ear. Finally, mirroring what was observed in patients with unilateral hearing loss, the extent of restoration of contralateral dominance was directly correlated with the ability to localize sounds after implantation. Altogether, we clearly demonstrated a link between brain reorganization and spatial auditory performance in deafness. Our results are crucial for further progress in the rehabilitation of unilaterally deaf patients and show that the success of rehabilitation depends mainly on brain plasticity mechanisms, and that the restoration of contralateral dominance is essential for an optimal functional recovery.

NEURAL CORRELATES OF PERCEPTUAL INVARIANCE IN THE FERRET AUDITORY CORTEX

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Carla Griffiths[1], Joseph Sollini[2], Jules Lebert[1], Jennifer Bizley[1]
[1]University College London, Ear Institute, London, United Kingdom, [2]University of Nottingham, Faculty Of Medicine & Health Sciences, Nottingham, United Kingdom

Perceptual invariance, the act of recognising auditory objects across identity-preserving variation and in the presence of other auditory stimuli, is critical to everyday listening. In this study, we tested whether perceptual invariance towards an auditory object can be established in the ferret auditory cortex (AC) and whether the AC encodes auditory object perception. To test perceptual invariance, we trained four ferrets in a Go/No-Go task where ferrets identified a target word ("instruments") from a stream drawn from 54 other British English words (distractors) before manipulating the mean fundamental frequency (F0) within and across trials.
We recorded AC neural activity using an Omnetics-WARP32 implant in one ferret and considered sites with a sound-onset response for Euclidean distance decoding. We computed a decoding score for pairwise discrimination of the target word from seven distractors, the target word reversed, and pink noise spectro-temporally matched to the target word. Decoder performance was above-chance and invariant when classifying between F0-manipulated distractor and target stimuli for both F0 manipulations across and within trials, whereas the discrimination performance of the neural responses of distractor versus distractor words was below-chance for most sites. Most sites decoded the behavioural perception of the target as the target or distractor at above-chance levels for both F0-manipulated and control trials.
Our preliminary results suggest that auditory objects are represented in the AC, that these neural responses are resistant to F0 change, and align with the behavioural perception of auditory stimuli rather than the ground-truth classification of the stimuli itself.

Single Cell and Single Nucleus RNA-Seq Reveal Cellular Heterogeneity and Homeostatic Regulatory Networks in Adult Mouse Stria Vascularis.
The stria vascularis (SV) generates the endocochlear potential (EP) in the inner ear and is necessary for proper hair cell mechanotransduction and hearing. While channels belonging to SV cell types are known to play crucial roles in EP generation, relatively little is known about gene regulatory networks that underlie the ability of the SV to generate and maintain the EP. Using single cell and single nucleus RNA-sequencing, we identify and validate known and rare cell populations in the SV. Furthermore, we establish a basis for understanding molecular mechanisms underlying SV function by identifying potential gene regulatory networks as well as druggable gene targets. Finally, we associate known deafness genes with adult SV cell types. This work establishes a basis for dissecting the genetic mechanisms underlying the role of the SV in hearing and will serve as a basis for designing therapeutic approaches to hearing loss related to SV dysfunction.

Grouping stimuli into abstract categories is a fundamental task of sensory systems. In the context of speech perception, the neuronal processes underlying the ability to reliably identify words from various speakers are not fully explained. Studies focusing on cortical fMRI responses have shown that secondary auditory areas respond differently to speech and artificial stimuli capturing the spectro-temporal modulations of speech (“model-matched stimuli”), suggesting that speech recognition depends on higher order cues represented in secondary auditory areas. This result was not replicated in naive ferrets. In this pilot study, we investigated whether ferrets can be trained to categorize human words and if this ability rely on higher order cues. One ferret was trained to discriminate fifteen versions of one human word (“target word”) against 50 other words (“non-target word”) in a two-alternative forced choice paradigm. When the animal was successfully trained, unrewarded probe trials were introduced to test the animal’s response to unknown versions of the target word, unknown words, model-matched versions of the target word, model-matched version of the non-target word, and model-matched version of an unknown word. Our behavioral results show that ferrets can be trained to reliably classify human words. The ferret significantly classified model-matched versions of the target and non-target words into the corresponding categories. These results could be partially mimicked by a linear classifier trained on modeled cortical representations of the target and non-target words. These results suggest that, even after training, ferrets rely on spectro-temporal cues to categorize new complex acoustic stimuli.

CORTICAL REPRESENTATIONS OF BACKGROUND AND FOREGROUND SOUNDS IN DYNAMICALLY-CHANGING SOUND MIXTURES

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Yves Boubenec, Agnès Landemard
ENS, Cognitive Studies, Paris, France

Humans and other animals constantly filter out complex background sounds in order to extract behaviorally-relevant signals of interest. The stage at which invariant representations emerge remains unclear, as adaptation to background noise has been observed at various levels in the auditory hierarchy. Using functional Ultrasound imaging (fUS), a recently developed technique based on blood flow imaging, we investigated responses to mixtures of natural foregrounds and backgrounds in ferret auditory cortex. Our paradigm consisted in presenting continuous mixture streams with periodic changes in background, as well as both components in isolation (**A**). Foregrounds included speech, music, and other non-stationary sounds, while backgrounds were chosen among the most stationary natural sounds, typically similar to sound textures (**B**). We found that fUS activity dynamically encoded changes in the stimuli (**C**) in a way that reflected stimulus stationarity, making it a powerful tool to study the dynamics of adaptation. We found that both background and foreground information were continuously encoded in cortical activity (**D-E**). In both primary and nonprimary regions, we observed overlapping populations encoding both foregrounds and backgrounds. Our results suggest that auditory cortex builds invariant representations by simultaneously storing a representation of complex backgrounds. Decoupling of signals can be operated by voxels' tuning to features that are characteristic of each type of

sounds.

ANATOMICAL ORGANIZATION OF THE MOUSE AUDITORY-PREFRONTAL CIRCUIT

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Felix Jung[1], Moritz Stingl[1], Sofie Ährlund-Richter[2], Josina Van Lunteren[1], Marina Slashcheva[1], Pierre Le Merre[1], Konstantinos Meletis[1], Marie Carlen[1]
[1]Karoliska Institutet, Neuroscience, Stockholm, Sweden, [2]Picower Institute for Learning and Memory, Brain And Cognitive Science, Cambridge, United States of America

The prefrontal cortex (PFC) in the frontal lobes of the mammalian brain is considered to constitute the highest stage of cognitive processing and to be critically involved in the generation and evaluation of adaptive and intentional behaviors. Fundamental to these processes is the integration of sensory information (feedforward) with state and goal information in prefrontal networks. The processing of sensory information in primary sensory cortices is heavily influenced by predictive signals generated in the PFC that are transmitted to sensory cortices (feedback).
In the present study, we aimed at dissecting the anatomical organization of both feedforward and feedback connections in the auditory-prefrontal circuit. By combining viral tools for anterograde and retrograde circuit tracing in combination with semi-automated cell segmentation and brain registration to the Allen Common Coordinate Framework, we generated a whole-brain input-output connectivity map of the auditory-prefrontal circuit.
Our results highlight the central role of the orbital subregions of the PFC as a putative hub for input-output transformation of auditory information as these regions are densely innervated by auditory axons and in turn possess the highest number of cells projecting to the auditory cortices. In conclusion, our results identified key nodes of the auditory-prefrontal circuit opening the possibility for its functional interrogation by future research.

INHIBITING PRESYNAPTIC CALCIUM CHANNEL MOBILITY IN THE AUDITORY CORTEX SUPPRESSES SYNCHRONIZED INPUT PROCESSING

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Katrina Deane[1,2], Ruslan Klymentiev[1,2], Jennifer Heck[3], Melanie Mark[4], Frank Ohl[1,3], Martin Heine[5], Max Happel[6]
[1]Leibniz Institute for Neurobiology, Systems Physiology Of Learning, Magdeburg, Germany, [2]Institute of Biology, Molecular Neurobiology, Magdeburg, Germany, [3]EMBL Heidelberg, Eipod, Heidelberg, Germany, [4]Ruhr-University Bochum, Behavioral Neurobiology, Bochum, Germany, [5]Institute of Developmental Biology and Neurobiology, Neurobiology, Mainz, Germany, [6]MSB Medical School Berlin, Medical Faculty, Berlin, Germany

Voltage gated calcium channels (VGCCs) trigger the influx of calcium to the presynaptic bouton during action-potential depolarization to release neurotransmitters, which happens probabilistically. When neuronal VGCCs were acutely aggregated using the optogenetic clustering of an cryptochrome mutant , CRY2olig, cultured primary hippocampal neurons generated a strong and reliable paired-pulse depression of consecutive responses compared to controls. While this method was used *in vitro* to render single cell firing to be more predictable, our aim was to observe how this would affect a neuronal network *in vivo*. In the primary auditory cortex (A1), we coupled VGCCs to Cry2olig via a feed-back-controlled anti GFP-intrabody, delivered by lentivirus, into a transgenic mouse model with a Citrine tag on the N terminus of all VGCCs. We recorded local field potentials down the depth of the A1 using a shaft electrode and transformed these into current source density (CSD) profiles over consecutive measurements under ketamine anesthesia before and after VGCC aggregation. Cortical response to auditory stimuli in the form of click trains and amplitude modulated tones was recorded. We demonstrated through cortical layer activity and average rectified CSD profiles VGCC clustering caused a significant suppression of response to both stimuli mainly due to suppressed sensory impulse responses. Our findings reveal the importance VGCC variability in neuronal networks and provide evidence that their membrane mobility may serve as an important maintenance feature during sensory encoding by dynamically adjusting network activity—especially in cases of very high cortical recruitment when the network is less capable of adapting.

LONG-TERM INTEGRATION OF SEQUENTIAL INFORMATION IN A SONGBIRD AUDITORY-PREMOTOR NUCLEUS

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Catherine Del Negro[1], Aurore Cazala[2], Xavier Hinaut[3], Nicolas Giret[1]
[1]Institut des Neurosciences Paris Saclay, Cnrs, Université Paris Saclay, Saclay, France, [2]NeuroPSI, Cogcomp, Orsay, France, [3]UMR 5293 - CNRS/Université de Bordeaux, Centre Broca Nouvelle Aquitaine, Bordeaux, France

Human speech and vocalizations of some non-human animal species consist of hierarchically organized sequences of vocal sounds that convey meaning in both their acoustic features and their sequential patterns. Computation of short and long-range statistical regularities has been proposed as a solution to extract information from these vocal streams. Humans are capable of computing not only adjacent sound regularities, transitional probabilities being higher between two syllables within words than at word boundaries, but also regularities among words that are quite distant from one another in a sentence. Understanding how the brain encodes statistically structured sequences of sounds, remains to be investigated, especially at the neuronal level. To address this issue, we took advantage of the complex sequential structure of canary song, in which the ordering of song elements, called phrases, depends on transitional probabilities and leads to the formation of recurrent sequences of two or more phrases. We recorded auditory responses in the auditory-premotor nucleus HVC (proper name), where neurons show selective responses to playback of their own vocalizations. As stimuli, we presented one bird's own song and versions of this song in which we manipulated its sequential structure. Results from 336 neurons in eight birds showed that changing the order of sequences without altering the order of phrases within sequences strongly affected the strength of responses while reordering only phrases did not. This suggests sensivity to the context that extends over several phrases, i.e. several seconds and, therefore to long-range regularities.

ASYNCHRONOUS DEVELOPMENT OF DEVIANCE DETECTION IN THE MOUSE CENTRAL AUDITORY SYSTEM

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Patricia Valerio[1], Julien Rechenmann[2], Mari Nakamura[1], Tania Barkat[1]
[1]University of Basel, Department Of Biomedicine, Basel, Switzerland, [2]Consultant Services, Rechenmann Data, Aarau, Switzerland

An essential task for our brain is to separate rare from common sensory inputs, defined as deviance detection. Previously characterized in adult humans and animals, deviance detection has most commonly been studied using an oddball paradigm, comprising sequences of common - standard - and rare - deviant - stimuli. These studies associated two mechanisms with deviance detection: stimulus-specific adaptation (SSA) and prediction error (PE). It is, however, still unknown whether deviance detection changes during postnatal development and what neuronal circuits might be involved. Using in vivo awake electrophysiological recordings, we studied this process in the central auditory system of adolescent mice. We observed an asynchronous development of deviance detection across the central auditory system: although already stable at postnatal day 20 (P20) in the inferior colliculus, deviance detection develops until P30 in the auditory thalamus, and even later in the primary auditory cortex (A1). These developmental changes seem related to PE maturation, as our oddball paradigm does not show SSA. We associated the observed alterations in A1 with a later maturation of deep layers across cell types. We are currently studying whether corticofugal projections are involved in the maturation of deviance detection in the auditory thalamus. Overall, our results show distinct deviance detection development across the central auditory areas during adolescence and identify a number of different mechanisms underlying it. Together, they support the importance of juvenile plasticity for the refinement of sensory processing. More generally, they will help understand prediction errors and surprise across sensory systems.

CONSEQUENCES OF EARLY-ONSET MILD HEARING LOSS ON BRAIN AND BEHAVIOR IN RATS.

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Joelle Jagersma[1], Sonja Pyott[1], Jocelien Olivier[2]
[1]University Medical Center Groningen, Department Of Otorhinolaryngology, Groningen, Netherlands, [2]University of Groningen, Department Of Neurobiology, Groningen, Netherlands

Background Extensive research indicates that children with hearing loss show intellectual and social interaction disabilities. To identify possible mechanisms, a rat model of mild (noise-induced) hearing loss was developed. This model was behaviorally phenotyped for cognitive and social functioning. Involved brain regions were immunologically and histologically investigated. Methods Hearing loss was induced in four-week-old Wistar rats and quantified through auditory brainstem responses (ABR). A behavioral test battery assessed social behavior when rats were 5 and 10 weeks old and novel object recognition (NOR) when rats were 8 weeks old. Thickness of cortical regions involved in cognitive and social behaviors and the size of the hippocampus were analyzed using cresyl violet staining. Neurogenesis in the hippocampus was analyzed using a marker for DCX. Results Mildly elevated auditory thresholds were found 2 weeks after noise exposure. During the NOR assessment, animals with mild hearing loss explored both the novel and familiar objects equally, suggesting reduced cognitive function compared to control (normal hearing) animals. No differences were found in social and play behaviors after hearing loss at either juvenile or adult ages. Additionally, no difference was found in neurogenesis in the hippocampus after mild hearing loss. Further neurobiological assessments focusing on plasticity, myelinization and neurotransmitter release in the involved regions are still under investigation. Conclusion Mild hearing loss in young rats induced cognitive impairment without overt neurobiological changes. Additional analyses will explore other neurobiological factors contributing to altered cognitive function.

INVESTIGATING CODING SCHEMES OF SPEECH AND MELODY IN AUDITORY CORTICAL AREAS.

POSTER SESSION 06 - SECTION: AUDITORY CORTEX

Akanksha Gupta[1], Agnès Trebuchon[1,2], Benjamin Morillon[1]
[1]Aix-Marseille University, Institut De Neuroscience Des Systèmes (ins), Umr Inserm 1106, Marseille, France, [2]Hôpital de la Timone, Service De Neurophysiologie Clinique, Marseille, France

We aim to understand the coding strategies employed by the two hemispheres during speech and melody processing using the spectro-temporal modulation framework (Flinker et al., 2019). Through this framework, Albouy and colleagues discovered a spatial code representing speech and melody in the left and right-associative auditory areas, respectively. We obtained intracranial EEG data from 11 epileptic patients who passively listened to three hundred *a cappella* stimuli, degraded in either temporal or spectral modulation dimensions or non-degraded. The stimulus set contained each sentence paired with each melody to allow uncoupling of the category (sentence or melody) specific information from general acoustic features. We performed a multiclass multivariate pattern analysis to classify the sentence or melodic contents within the temporal dimension of the raw signal. Results show accurate decoding of sentences in non-degraded and spectrally degraded conditions and melodies in non-degraded and temporally degraded conditions. This result corroborates the findings of a recent work showing a reduction in speech perception with temporal degradation and melody perception with spectral degradation (Albouy et al., 2020). Additionally, we observe correct decoding on stimulus time courses in primary and associative auditory areas. These preliminary results indicate the presence of a temporal code for speech and melody perception. Thus, further investigations are necessary to test if specific frequencies or connectivity patterns encode linguistic or melodic information. **This research was supported by the ANR-20-CE28-0007 grant.**

THE ROLE OF INHIBITORY INTERNEURONS IN CORTICAL ENGRAM FUNCTION AND MEMORY PROCESSING IN A MOUSE MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Julia Van Adrichem, Ronald Van Kesteren, Michel Van Den Oever
Vrije Universiteit Amsterdam, Center For Neurogenomics And Cognitive Research, Amsterdam, Netherlands

Memories are stored by sparse populations of neurons, i.e. engram cells, which increase their mutual synaptic connections upon learning. While hippocampal engrams store recent memories, prolonged storage depends on the medial prefrontal cortex (mPFC). Whether a neuron is recruited into an engram depends on its excitability during learning. Interestingly hippocampal inhibitory parvalbumin (PV) interneurons of APP/PS1 mice, a mouse model of Alzheimer's disease (AD), show altered excitability. However, it is unclear whether these interneurons alter engram functioning, and how this contributes to memory decline in AD. To study engram functioning in relation to memory decline, APP/PS1 mice were exposed to contextual fear conditioning. Activated neurons were tagged using viral-TRAP. Four weeks after training, remote memory retrieval was examined and brains were isolated for immunohistochemistry. Furthermore, patch-clamp recordings were used to study neuronal excitability in the mPFC. Remote memory was impaired in 20-week-old APP/PS1 mice. During remote memory retrieval, reduced neuronal activation (Fos expression) was observed in the mPFC, and interestingly, also a lower percentage of GAD67-expressing cells. At 16 weeks of age, no memory impairment was detected yet and mPFC PV cell excitability was unaltered, however, pyramidal cells showed signs of hyperexcitability. Although mPFC pyramidal cell properties appear to be altered before the onset of memory retrieval deficits, this might already affect memory formation at this age and subsequent retrieval at a later age (e.g. 20 weeks). Ongoing experiments aim to reveal alterations in neuronal excitability over time and whether engram function is altered in AD mice.

Persistence is a key characteristic of memory that relies on **systems consolidation**, a process classically defined as the gradual transfer of information from the hippocampus to the cortex for long-term memory storage.
However, the underlying molecular mechanisms are unknown. **DNA methylation** can act as a long-term regulatory signal, therefore being a prime candidate to regulate memory duration and stabilisation within **neuronal ensembles** – the physical substrate of a memory.
Using contextual fear conditioning (CFC) and ensemble tagging tools in mice, we showed that reactivation of cortical ensembles reflects systems consolidation. We found higher engagement of cortical ensembles selectively in persistent fear memory. To address whether **DNA methylation underlies persistent memory storage and neuronal ensemble reactivation**, we overexpressed a DNA Methyltransferase (DNMT3a2) in the dorsal hippocampus of mice during CFC. Strikingly, we found a **conversion of short-lasting into long-lasting memory**. Moreover, we found an **improved reactivation of cortical neuronal ensembles** and increased **fear generalisation**, mimicking the ensemble dynamics and behavioural trait of persistent memory, respectively. To uncover the molecular targets of DNMT3a2 activity, we next performed RNA-Sequencing analysis of dorsal hippocampi of mice overexpressing DNMT3a2. We found eight **differentially expressed genes** that might have a **mechanistic involvement in memory persistence** downstream of DNMT3a2-mediated DNA methylation.
In summary, we found that overexpressing DNMT3a2 in dorsal hippocampus converts a short-lasting into a persistent memory by stabilising cortical neuronal ensembles. **These findings suggest that hippocampal DNMT3a2 facilitates systems consolidation.**

The angiopoietin-Tie2 pathway regulates Purkinje cell dendritic morphogenesis in a cell-autonomous manner.
Neuro-vascular communication is essential to synchronize central nervous system development. Here, we identify angiopoietin/Tie2 as a neuro-vascular signaling axis involved in regulating dendritic morphogenesis of Purkinje cells (PCs). We show that in the developing cerebellum Tie2 expression is not restricted to blood vessels, but it is also present in PCs. Its ligands angiopoietin-1 (Ang1) and angiopoietin-2 (Ang2) are expressed in neural cells and endothelial cells (ECs), respectively. PC-specific deletion of Tie2 results in reduced dendritic arborization, which is recapitulated in neural-specific Ang1-knockout and Ang2 full-knockout mice. Mechanistically, RNA sequencing reveals that Tie2-deficient PCs present alterations in gene expression of multiple genes involved in cytoskeleton organization, dendritic formation, growth, and branching. Functionally, mice with deletion of Tie2 in PCs present alterations in PC network functionality. Altogether, our data propose Ang/Tie2 signaling as a mediator of intercellular communication between neural cells, ECs, and PCs, required for proper PC dendritic morphogenesis and function.

Engram reactivation during memory retrieval predicts long-term memory performance in aged mice.
Age-related cognitive decline preferentially targets long-lasting episodic memories that require intact hippocampal function. Memory traces (or engrams) are believed to be encoded within the neurons activated during learning (neuronal ensembles), and recalled by reactivation of the same population. However, whether engram reactivation dictates memory performance late in life is not known. Here, we labeled neuronal ensembles formed during object location recognition learning in the

dentate gyrus, and analyzed the reactivation of this population during long-term memory recall in young adult, cognitively impaired- and unimpaired-aged mice. We found that reactivation of memory-encoding neuronal ensembles at long-term memory recall was disrupted in impaired but not unimpaired-aged mice. Furthermore, we showed that the memory performance in the aged population correlated with the degree of engram reactivation at long-term memory recall. Overall, our data implicates recall-induced engram reactivation as a prediction factor of memory performance in aging. Moreover, our findings suggest impairments in neuronal ensemble stabilization and/or reactivation as an underlying mechanism in age-dependent cognitive decline.

Molecular and cellular mechanisms of engram allocation and maintenance.
Understanding how we learn and remember has been a long-standing question in neuroscience. Technological developments of the past 15 years have allowed for dramatically increased access to the neurons that hold the physical representation of memory, also known as a memory trace or engram. Such developments have tremendously facilitated advancement of the memory field, since they made possible interrogation of the cellular and molecular mechanisms underlying memory formation with unprecedented cellular specificity. Here, we discuss the studies that have investigated rules governing neuronal recruitment to a particular memory engram. Furthermore, we provide an overview of the evidence that functional and structural changes associated with memory consolidation occur in engram neurons. Moreover, we summarize the expanding literature showing that transcriptional regulatory factors such as transcription factors and epigenetic mechanisms play an important role in the maintained allocation of behaviorally-selected neurons to an engram. Together, these studies have begun elucidating how neuronal networks are selected and modified in order to support memory formation and storage.

MeCP2 gates spatial learning-induced alternative splicing events in the mouse hippocampus.
Long-term memory formation is supported by functional and structural changes of neuronal networks, which rely on de novo gene transcription and protein synthesis. The modulation of the neuronal transcriptome in response to learning depends on transcriptional and post-transcriptional mechanisms. DNA methylation writers and readers regulate the activity-dependent genomic program required for memory consolidation. The most abundant DNA methylation reader, the Methyl CpG binding domain protein 2 (MeCP2), has been shown to regulate alternative splicing, but whether it establishes splicing events important for memory consolidation has not been investigated. In this study, we identified the alternative splicing profile of the mouse hippocampus in basal conditions and after a spatial learning experience, and investigated the requirement of MeCP2 for these processes. We observed that spatial learning triggers a wide-range of alternative splicing events in transcripts associated with structural and functional remodeling and that virus-mediated knockdown of MeCP2 impairs learning-dependent post-transcriptional responses of mature hippocampal neurons. Furthermore, we found that MeCP2 preferentially affected the splicing modalities intron retention and exon skipping and guided the alternative splicing of distinct set of genes in baseline conditions and after learning. Lastly, comparative analysis of the MeCP2-regulated transcriptome with the alternatively spliced mRNA pool, revealed that MeCP2 disruption alters the relative abundance of alternatively spliced isoforms without affecting the overall mRNA levels. Taken together, our findings reveal that adult hippocampal MeCP2 is required to finetune alternative splicing events in basal conditions, as well as in response to spatial learning. This study provides new insight into how MeCP2 regulates brain function, particularly cognitive abilities, and sheds light onto the pathophysiological mechanisms of Rett syndrome, that is characterized by intellectual disability and caused by mutations in the Mecp2 gene.

Modeling human age-associated increase in Gadd45γ expression leads to spatial recognition memory impairments in young adult mice.
Aging is associated with the progressive decay of cognitive function. Hippocampus-dependent processes, such as the formation of spatial memory, are particularly vulnerable to aging. Currently, the molecular mechanisms responsible for age-dependent cognitive decline are largely unknown. Here, we investigated the expression and function of the growth arrest DNA damage gamma (Gadd45γ) during aging and cognition. We report that Gadd45γ expression is increased in the hippocampus of aged humans and that Gadd45γ overexpression in the young adult mouse hippocampus compromises cognition. Moreover, Gadd45γ overexpression in hippocampal neurons disrupted cAMP response element-binding protein signaling and the expression of well-established activity-regulated genes. This work shows that Gadd45γ expression is tightly controlled in the hippocampus and its disruption may be a mechanism contributing to age-related cognitive impairments observed in humans.

Neuronal ensemble-specific DNA methylation strengthens engram stability.
Memories are encoded by memory traces or engrams, represented within subsets of neurons that are synchronously activated during learning. However, the molecular mechanisms that drive engram stabilization during consolidation and consequently ensure its reactivation by memory recall are not fully understood. In this study we manipulate, during memory consolidation, the levels of the de novo DNA methyltransferase 3a2 (Dnmt3a2) selectively within dentate gyrus neurons activated by fear conditioning. We found that Dnmt3a2 upregulation enhances memory performance in mice and improves the fidelity of reconstitution of the original neuronal ensemble upon memory retrieval. Moreover, similar manipulation in a sparse, non-engram subset of neurons does not bias engram allocation or modulate memory strength. We further show that neuronal Dnmt3a2 overexpression changes the DNA methylation profile of synaptic plasticity-related genes. Our data implicates DNA methylation selectively within neuronal ensembles as a mechanism of stabilizing engrams during consolidation that supports successful memory retrieval.

Mimicking Age-Associated Gadd45γ Dysregulation Results in Memory Impairments in Young Adult Mice.
Age-related memory loss is observed across multiple mammalian species and preferentially affects hippocampus-dependent memory. Memory impairments are characterized by accelerated decay of spatial memories. Nevertheless, the molecular mechanisms underlying these deficits are still largely unknown. Here, we investigated the expression and function of the growth arrest DNA damage (Gadd45) family during aging and cognition, respectively. We report that aging impairs the expression of Gadd45γ in the hippocampus of cognitively impaired male mice. Mimicking this decrease in young adult male mice led to age-like memory deficits in hippocampus-dependent memory tasks. Gadd45γ reduction impaired the activity of key components of the mitogen-activated protein kinase (MAPK) pathway (p38 and JNK) in mouse hippocampal cultures. Furthermore, we found that activation of downstream targets, such as ATF-2, c-Jun, and CREB (cAMP response element-binding protein), was disrupted. Finally, we showed that Gadd45γ is required for induction of key early- and late-response genes that have been associated with aging. Together, these findings indicate that Gadd45γ expression regulates cognitive abilities and synapse-to-nucleus communication and suggest Gadd45γ dysfunction as a potential mechanism contributing to age-related cognitive impairments. A high percentage of subjects experience age-related memory loss that burdens daily performance. Although many advances have been made, the precise changes in the brain governing these deficits are unclear. Identifying molecular processes that are required for cognition and are altered during old age is crucial to develop preventive or therapeutic strategies. Here, we show that baseline and learning-induced expression of the growth arrest DNA damage (Gadd45) γ is selectively impaired in the hippocampus of aged mice with cognitive deficits. Next, we show that modeling this impairment in young adult mice with normal cognitive performance disrupts long- and short-term memories in an age-like manner. Finally, we demonstrate that Gadd45γ regulates synapse-to-nucleus communication processes that are needed for plasticity-associated gene expression.

Quiescence Modulates Stem Cell Maintenance and Regenerative Capacity in the Aging Brain.
The function of somatic stem cells declines with age. Understanding the molecular underpinnings of this decline is key to counteract age-related disease. Here, we report a dramatic drop in the neural stem cells (NSCs) number in the aging murine brain. We find that this smaller stem cell reservoir is protected from full depletion by an increase in quiescence that makes old NSCs more resistant to regenerate the injured brain. Once activated, however, young and old NSCs show similar proliferation and differentiation capacity. Single-cell transcriptomics of NSCs indicate that aging changes NSCs minimally. In the aging brain, niche-derived inflammatory signals and the Wnt antagonist sFRP5 induce quiescence. Indeed, intervention to neutralize them increases activation of old NSCs during homeostasis and following injury. Our study identifies quiescence as a key feature of old NSCs imposed by the niche and uncovers ways to activate NSCs to repair the aging brain.

Possible role of calcitonin gene-related peptide in trigeminal modulation of glomerular microcircuits of the rodent olfactory bulb.
Chemosensation in the mammalian nose comprises detection of odorants, irritants and pheromones. While the traditional view assigned one distinct sub-system to each stimulus type, recent research has produced a more complex picture.

Odorants are not only detected by olfactory sensory neurons but also by the trigeminal system. Irritants, in turn, may have a distinct odor, and some pheromones are detected by the olfactory epithelium. Moreover, it is well established that irritants change odor perception and vice versa. A wealth of psychophysical evidence on olfactory-trigeminal interactions in humans contrasts with a paucity of structural insight. In particular, it is unclear whether the two systems communicate just by sharing stimuli, or whether neuronal connections mediate cross-modal signaling. One connection could exist in the olfactory bulb that performs the primary processing of olfactory signals and receives trigeminal innervation. In the present study, neuroanatomical tracing of the mouse ethmoid system illustrates how peptidergic fibers enter the glomerular layer of the olfactory bulb, where local microcircuits process and filter the afferent signal. Biochemical assays reveal release of calcitonin gene-related peptide from olfactory bulb slices and attenuation of cAMP signaling by the neuropeptide. In the non-stimulated tissue, the neuropeptide specifically inhibited the basal activity of calbindin-expressing periglomerular interneurons, but did not affect the basal activity of neurons expressing calretinin, parvalbumin, or tyrosine hydroxylase, nor the activity of astrocytes. This study represents a first step towards understanding trigeminal neuromodulation of olfactory-bulb microcircuits and provides a working hypothesis for trigeminal inhibition of olfactory signal processing.

Both long-term synaptic plasticity and long-term memory formation require *de novo* gene transcription and protein synthesis. Epigenetic and chromatic remodeling are known to be the primary molecular mechanisms responsible for changing gene expression patterns in neuronal and non-neuronal cells. Previous studies indicate that histone deacetylases (HDACs) are key enzymes that regulate chromatin remodeling and gene expression during memory formation. Indeed, genetic or pharmacological inhibition of HDAC produces robust improvements in long-term memory in multiple learning paradigms in rodents. Moreover, these HDACs are recruited by several transcriptional repressors, including Switch-Insensitive 3A (SIN3A). Interestingly, SIN3A is a large scaffold protein whose role in memory formation was recently discovered *(Bridi et al., 2020)*. Here, we postulate that preventing the recruitment of HDACs to the chromatin by inhibiting the action of SIN3A will improve memory capacities by the increasing the expression of plasticity-related genes in mice. To test our hypothesis, we used a viral strategy to reduce SIN3A expression in adult mice hippocampus. We then assessed the memory capacities of these mice using several behavioral paradigms. In the future, the expression of plasticity-related genes will be monitored. Today, anti-aging strategies have focused their effort on HDAC modulation. Since SIN3A plays important role in HDAC-mediated transcriptional repression, we believe that understanding its function in mature neurons could provide links between chromatin structure and gene activity during age-associated cognitive decline.

Aims: Peripheral inputs to the brain continuously shape its function and can influence the formation of memory. Cannabinoid type-1 receptor (CB1R) is a well-recognized player in memory performance. Our group has previously demonstrated that the acute peripheral CB1R blockade in mice participates in the modulation of memory persistence. Here, we aim to evaluate the behavioral, cellular and molecular outcome of a sub-chronic blockade of peripheral CB1R in mice. **Methods:** Male young adult mice received a sub-chronic 7 days treatment with the peripherally-restricted CB1R antagonist AM6545. We evaluated memory performance using the novel object-recognition test and executive function with the pairwise discrimination task. Hippocampal synaptic plasticity and cell proliferation, as well as the expression of neurotrophic factors by immunoblot and q-PCR were also evaluated as treatment outcomes. **Results:** We found that sub-chronic administration of AM6545 resulted in enhanced recognition memory under basal and challenging conditions. In addition, executive function was facilitated after repeated AM6545 administration. Interestingly, AM6545 treatment occluded long-term potentiation in hippocampal synapses and increased the hippocampal expression of Bdnf and Ngf neurotrophic factors, while it did not modify cell proliferation in the subgranular zone of the dentate gyrus. **Conclusions:** Our results suggest that peripheral CB1R contributes to the modulation of memory persistence, executive function and hippocampal synaptic plasticity in mice, mimicking to some extent the effects of systemic approaches reducing CB1R function. **Acknowledgements:** This work was supported by *Generalitat de Catalunya* (FI-2020), *Ministerio de Economía, Innovación y Competitividad* (MINECO), Spain (#RTI2018-099282-B-I00B).

THE ROLE OF YOUNG ADULT-BORN NEURONS IN PATTERN SEPARATION

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Charlotte Castillon, John Armstrong, Anis Contractor
Northwestern University, Neuroscience, CHICAGO, United States of America

The birth and incorporation of new neurons into the dentate gyrus of the hippocampus of adult mice has been deemed important for many forms of hippocampal dependent behaviors and memory. Postmitotic adult-born dentate granule cells (abDGCs) mature over several weeks and eventually have similar properties to developmentally born neurons. During this postmitotic maturation process abDGCs display unique properties that potentially underlie their involvement in distinct aspects of hippocampal function. Despite this, it remains unknown how effectively these neurons are engaged and contribute to relevant behaviors during their maturation. In particular, a role has been described for abDGCs in pattern separation (PS), a memory function that enables discrimination of similar but distinct representations into non-overlapping memories. Yet many questions remain about when and how these neurons facilitate an animal's ability to discriminate similar situations. In this study we proposed to directly determine when and how abDGCs are activated when mice perform a PS task and assess their maturation stage and functional characteristics. To do this we developed a custom automated touch screen PS paradigm and determined which neurons were active during different phases of the learning process using a reporter mouse that allows Targeted Recombination in Active Populations (TRAP2). Combining this with birth-dating of neurons we are determining which cohorts of abDGCs are active and using ex-vivo single-cell patch-clamp to assess if they possess distinct functional properties. These studies will ultimately refine our understanding of how abDGCs are functionally incorporated into the hippocampal network and how they contribute to PS.

Pulse-Chase Proteomics of the App Knockin Mouse Models of Alzheimer's Disease Reveals that Synaptic Dysfunction Originates in Presynaptic Terminals.
Compromised protein homeostasis underlies accumulation of plaques and tangles in Alzheimer's disease (AD). To observe protein turnover at early stages of amyloid beta (Aβ) proteotoxicity, we performed pulse-chase proteomics on mouse brains in three genetic models of AD that knock in alleles of amyloid precursor protein (APP) prior to the accumulation of plaques and during disease progression. At initial stages of Aβ accumulation, the turnover of proteins associated with presynaptic terminals is selectively impaired. Presynaptic proteins with impaired turnover, particularly synaptic vesicle (SV)-associated proteins, have elevated levels, misfold in both a plaque-dependent and -independent manner, and interact with APP and Aβ. Concurrent with elevated levels of SV-associated proteins, we found an enlargement of the SV pool as well as enhancement of presynaptic potentiation. Together, our findings reveal that the presynaptic terminal is particularly vulnerable and represents a critical site for manifestation of initial AD etiology. A record of this paper's transparent peer review process is included in the Supplemental Information.

Recruitment of parvalbumin and somatostatin interneuron inputs to adult born dentate granule neurons.
GABA is a key regulator of adult-born dentate granule cell (abDGC) maturation so mapping the functional connectivity between abDGCs and local interneurons is required to understand their development and integration into the hippocampal circuit. We recorded from birthdated abDGCs in mice and photoactivated parvalbumin (PV) and somatostatin (SST) interneurons to map the timing and strength of inputs to abDGCs during the first 4 weeks after differentiation. abDGCs received input from PV interneurons in the first week, but SST inputs were not detected until the second week. Analysis of desynchronized quantal events established that the number of GABAergic synapses onto abDGCs increased with maturation, whereas individual synaptic strength was constant. Voluntary wheel running in mice scaled the GABAergic input to abDGCs by increasing the number of synaptic contacts from both interneuron types. This demonstrates that GABAergic

innervation to abDGCs develops during a prolonged post-mitotic period and running scales both SST and PV synaptic afferents.

The intellectual disability PAK3 R67C mutation impacts cognitive functions and adult hippocampal neurogenesis.
The link between mutations associated with intellectual disability (ID) and the mechanisms underlying cognitive dysfunctions remains largely unknown. Here, we focused on PAK3, a serine/threonine kinase whose gene mutations cause X-linked ID. We generated a new mutant mouse model bearing the missense R67C mutation of the Pak3 gene (Pak3-R67C), known to cause moderate to severe ID in humans without other clinical signs and investigated hippocampal-dependent memory and adult hippocampal neurogenesis. Adult male Pak3-R67C mice exhibited selective impairments in long-term spatial memory and pattern separation function, suggestive of altered hippocampal neurogenesis. A delayed non-matching to place paradigm testing memory flexibility and proactive interference, reported here as being adult neurogenesis-dependent, revealed a hypersensitivity to high interference in Pak3-R67C mice. Analyzing adult hippocampal neurogenesis in Pak3-R67C mice reveals no alteration in the first steps of adult neurogenesis, but an accelerated death of a population of adult-born neurons during the critical period of 18-28 days after their birth. We then investigated the recruitment of hippocampal adult-born neurons after spatial memory recall. Post-recall activation of mature dentate granule cells in Pak3-R67C mice was unaffected, but a complete failure of activation of young DCX + newborn neurons was found, suggesting they were not recruited during the memory task. Decreased expression of the KCC2b chloride cotransporter and altered dendritic development indicate that young adult-born neurons are not fully functional in Pak3-R67C mice. We suggest that these defects in the dynamics and learning-associated recruitment of newborn hippocampal neurons may contribute to the selective cognitive deficits observed in this mouse model of ID.

Selective alteration of adult hippocampal neurogenesis and impaired spatial pattern separation performance in the RSK2-deficient mouse model of Coffin-Lowry syndrome.
Adult neurogenesis is involved in certain hippocampus-dependent cognitive functions and is linked to psychiatric diseases including intellectual disabilities. The Coffin-Lowry syndrome (CLS) is a developmental disorder caused by mutations in the Rsk2 gene and characterized by intellectual disabilities associated with growth retardation. How RSK2-deficiency leads to cognitive dysfunctions in CLS is however poorly understood. Here, using Rsk2 Knock-Out mice, we characterized the impact of RSK2 deficiency on adult hippocampal neurogenesis in vivo. We report that the absence of RSK2 does not affect basal proliferation, differentiation and survival of dentate gyrus adult-born neurons but alters the maturation progression of young immature newborn neurons. Moreover, when RSK2-deficient mice were submitted to spatial learning, in contrast to wild-type mice, proliferation of adult generated neurons was decreased and no pro-survival effect of learning was observed. Thus, learning failed to recruit a selective population of young newborn neurons in association with deficient long-term memory recall. Given the proposed role of the dentate gyrus and of adult-generated newborn neurons in hippocampal-dependent pattern separation function, we explored this function in a delayed non-matching to place task and in an object-place pattern separation task and report severe deficits in spatial pattern separation in Rsk2-KO mice. Together, this study reveals a previously unknown role for RSK2 in the early stages of maturation and learning-dependent involvement of adult-born dentate gyrus neurons. These alterations associated with a deficit in the ability of RSK2-deficient mice to finely discriminate relatively similar spatial configurations, may contribute to cognitive dysfunction in CLS.

EXPERIENCE- AND TIME-DEPENDENT SYNAPTIC ADAPTATIONS IN CORTICAL ENGRAM CELLS

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Miodrag Mitrić, Luca Van Leeuwen, Esther Visser, August Smit, Michel Van Den Oever
Vrije University Amsterdam, Center For Neurogenomics And Cognitive Research, Department Of Molecular And Cellular Neurobiology, Amsterdam, Netherlands

A remote contextual fear memory is encoded by neurons in the medial prefrontal cortex (mPFC) that are activated during learning, so-called engram cells. However, strong fear conditioning results in their disengagement. Here, we investigated whether physiological and structural plasticity of these neurons is associated with their temporal- and experience-dependent involvement in memory expression. We used TRAP2-tdTomato mice to tag and visualize mPFC neurons after mild (1 foot-shock; 1US) or strong (3 foot-shocks; 3US) contextual fear conditioning (CFC), or after context exposure alone (No Shock; NS). By performing patch-clamp recordings in tagged vs. non-tagged pyramidal neurons at a recent (≤ 1 week) or remote (~4 weeks) timepoint after conditioning, we observed no differences in intrinsic excitability, regardless of the timepoint or training intensity. However, we found progressive changes in physiological and structural properties of excitatory synapses on tagged mPFC neurons that were most pronounced after mild CFC. Our results indicate that specific excitatory inputs onto mPFC engram cells are selectively enhanced after mild conditioning, in line with the memory strength-dependent engagement of these neurons in remote memory expression.

The Medial Prefrontal Cortex as a Central Hub for Mental Comorbidities Associated with Chronic Pain.
Chronic pain patients frequently develop and suffer from mental comorbidities such as depressive mood, impaired cognition, and other significant constraints of daily life, which can only insufficiently be overcome by medication. The emotional and cognitive components of pain are processed by the medial prefrontal cortex, which comprises the anterior cingulate cortex, the prelimbic, and the infralimbic cortex. All three subregions are significantly affected by chronic pain: magnetic resonance imaging has revealed gray matter loss in all these areas in chronic pain conditions. While the anterior cingulate cortex appears hyperactive, prelimbic, and infralimbic regions show reduced activity. The medial prefrontal cortex receives ascending, nociceptive input, but also exerts important top-down control of pain sensation: its projections are the main cortical input of the periaqueductal gray, which is part of the descending inhibitory pain control system at the spinal level. A multitude of neurotransmitter systems contributes to the fine-tuning of the local circuitry, of which cholinergic and GABAergic signaling are particularly emerging as relevant components of affective pain processing within the prefrontal cortex. Accordingly, factors such as distraction, positive mood, and anticipation of pain relief such as placebo can ameliorate pain by affecting mPFC function, making this cortical area a promising target region for medical as well as psychosocial interventions for pain therapy.

Tissue Specific Reference Genes for MicroRNA Expression Analysis in a Mouse Model of Peripheral Nerve Injury.
MicroRNAs (miRNAs) have emerged as master switch regulators in many biological processes in health and disease, including neuropathy. miRNAs are commonly quantified by reverse transcription quantitative real-time polymerase chain reaction (RT-qPCR), usually estimated as relative expression through reference genes normalization. Different non-coding RNAs (ncRNAs) are used for miRNA normalization; however, there is no study identifying the optimal reference genes in animal models for peripheral nerve injury. We evaluated the stability of eleven ncRNAs, commonly used for miRNA normalization, in dorsal root ganglia (DRG), dorsal horn of the spinal cord (dhSC), and medial prefrontal cortex (mPFC) in the mouse spared nerve injury (SNI) model. After RT-qPCR, the stability of each ncRNA was determined by using four different methods: BestKeeper, the comparative delta-Cq method, geNorm, and NormFinder. The candidates were rated according to their performance in each method and an overall ranking list was compiled. The most stable ncRNAs were: sno420, sno429, and sno202 in DRG; sno429, sno202, and U6 in dhSC; sno202, sno420, and sno142 in mPFC. We provide the first reference genes' evaluation for miRNA normalization in different neuronal tissues in an animal model of peripheral nerve injury. Our

results underline the need for careful selection of reference genes for miRNA normalization in different tissues and experimental conditions. We further anticipate that our findings can be used in a broad range of nerve injury related studies, to ensure validity and promote reproducibility in miRNA quantification.

Layer- and subregion-specific electrophysiological and morphological changes of the medial prefrontal cortex in a mouse model of neuropathic pain.
Chronic neuropathic pain constitutes a serious public health problem, but the disease mechanisms are only partially understood. The involvement of different brain regions like the medial prefrontal cortex has already been established, but the comparison of the role of different subregions and layers is still inconclusive. In the current study, we performed patch-clamp recordings followed by anatomical reconstruction of pyramidal cells from different layers of the prelimbic and infralimbic subregions of the medial prefrontal cortex in neuropathic (spared nerve injury, SNI) and control mice. We found that in the prelimbic cortex, layer 2/3 pyramidal cells from SNI mice exhibited increased excitability compared to sham controls, whereas prelimbic layer 5 pyramidal neurons showed reduced excitability. Pyramidal cells in both layer 2/3 and layer 5 of the infralimbic subregion did not change their excitability, but layer 2/3 pyramidal cells displayed increased dendritic length and branching. Our findings support the view that chronic pain is associated with subregion- and layer-specific changes in the medial prefrontal cortex. They therefore provide new insights into the mechanisms underlying the chronification of pain.

Impaired mechanical, heat, and cold nociception in a murine model of genetic TACE/ADAM17 knockdown.
TNF-α-converting enzyme, a member of the ADAM (A disintegrin and metalloproteinase) protease family and also known as ADAM17, regulates inflammation and regeneration in health and disease. ADAM17 targets are involved in pain development and hypersensitivity in animal models of inflammatory and neuropathic pain. However, the role of ADAM17 in the pain pathway is largely unknown. Therefore, we used the hypomorphic ADAM17 (ADAM17) mouse model to investigate the importance of ADAM17 in nociceptive behavior, morphology, and function of primary afferent nociceptors. ADAM17 mice were hyposensitive to noxious stimulation, showing elevated mechanical thresholds as well as impaired heat and cold sensitivity. Despite these differences, skin thickness and innervation were comparable to controls. Although dorsal root ganglia of ADAM17 mice exhibited normal morphology of peptidergic and nonpeptidergic neurons, a small but significant reduction in the number of isolectin β-4-positive neurons was observed. Functional electrical properties of unmyelinated nociceptors showed differences in resting membrane potential, afterhyperpolarization, and firing patterns in specific subpopulations of sensory neurons in ADAM17 mice. However, spinal cord morphology and microglia activity in ADAM17 mice were not altered. Our data suggest that ADAM17 contributes to the processing of painful stimuli, with a complex mode of action orchestrating the function of neurons along the pain pathway.-Quarta, S., Mitrić, M., Kalpachidou, T., Mair, N., Schiefermeier-Mach, N., Andratsch, M., Qi, Y., Langeslag, M., Malsch, P., Rose-John, S., Kress, M. Impaired mechanical, heat, and cold nociception in a murine model of genetic TACE/ADAM17 knockdown.

Altered Gene Expression in Prefrontal Cortex of a Fabry Disease Mouse Model.
Fabry disease is an X-chromosome linked hereditary disease that is caused by loss of function mutations in the α-galactosidase A (α-Gal A) gene, resulting in defective glycolipid degradation and subsequent accumulation of globotriaosylceramide (Gb3) in different tissues, including vascular endothelial cells and neurons in the peripheral and central nervous system. We recently reported a differential gene expression profile of α-Gal A mouse dorsal root ganglia, an established animal model of Fabry disease, thereby providing new gene targets that might underlie the neuropathic pain related symptoms. To investigate the cognitive symptoms experienced by Fabry patients, we performed one-color based hybridization microarray expression profiling of prefrontal cortex samples from adult α-Gal A mice and age-matched wildtype controls, followed by protein-protein interaction and pathway analyses for the differentially regulated mRNAs. We found that from a total of 381 differentially expressed genes, 135 genes were significantly upregulated, whereas 246 genes were significantly downregulated between α-Gal A mice and wildtype controls. Enrichment analysis for downregulated genes revealed mainly immune related pathways, including immune/defense responses, regulation of cytokine production, as well as signaling and transport regulation pathways. Further analysis of the regulated genes revealed a large number of genes involved in neurodegeneration. The current analysis for the first time presents a differential gene expression profile of central nervous system tissue from α-Gal A mice, thereby providing novel knowledge on the deregulation and a possible contribution of gene expression to Fabry disease related brain pathologies.

Extinction of Cocaine Memory Depends on a Feed-Forward Inhibition Circuit Within the Medial Prefrontal Cortex.
Cocaine-associated environments (i.e., contexts) evoke persistent memories of cocaine reward and thereby contribute to the maintenance of addictive behavior in cocaine users. From a therapeutic perspective, enhancing inhibitory control over cocaine-conditioned responses is of pivotal importance but requires a more detailed understanding of the neural circuitry that can suppress context-evoked cocaine memories, e.g., through extinction learning. The ventral medial prefrontal cortex (vmPFC) and dorsal medial prefrontal cortex (dmPFC) are thought to bidirectionally regulate responding to cocaine cues through their projections to other brain regions. However, whether these mPFC subregions interact to enable adaptive responding to cocaine-associated contextual stimuli has remained elusive.

A Synaptic Framework for the Persistence of Memory Engrams.
The ability to store and retrieve learned information over prolonged periods of time is an essential and intriguing property of the brain. Insight into the neurobiological mechanisms that underlie memory consolidation is of utmost importance for our understanding of memory persistence and how this is affected in memory disorders. Recent evidence indicates that a given memory is encoded by sparsely distributed neurons that become highly activated during learning, so-called engram cells. Research by us and others confirms the persistent nature of cortical engram cells by showing that these neurons are required for memory expression up to at least 1 month after they were activated during learning. Strengthened synaptic connectivity between engram cells is thought to ensure reactivation of the engram cell network during retrieval. However, given the continuous integration of new information into existing neuronal circuits and the relatively rapid turnover rate of synaptic proteins, it is unclear whether a lasting learning-induced increase in synaptic connectivity is mediated by stable synapses or by continuous dynamic turnover of synapses of the engram cell network. Here, we first discuss evidence for the persistence of engram cells and memory-relevant adaptations in synaptic plasticity, and then propose models of synaptic adaptations and molecular mechanisms that may support memory persistence through the maintenance of enhanced synaptic connectivity within an engram cell network.

Aims:There is anatomical and electrophysiological evidence that median raphe region (MRR) vesicular glutamate transporter type 3 (VGLUT3) positive neurons project to the hippocampus and influence its activity. Our aim was to characterise the behavioural effects of MRR-VGLUT3+ neuronal activity during spatial learning and memory formation. Methods:We utilised chemogenetics (DREADDs) and optogenetics (ChR2) in VGLUT3-Cre mice in the hippocampus dependent Morris watermaze paradigm. VGLUT3-Cre male and female mice were injected with Cre-dependent adenoassociated viral vectors containing either control (RFP) or excitatory (G_q–GPCR/ChR2) sequences. During spatial reference memory (SRM) phase the chemogenetic groups were injected with CNO 30min before experiment. For optogenetics, blue laser was used at 20Hz for 10sec while on the platform. Short-term memory was assessed 10min after last learning trial, while long-term memory was studied at 72h. Results:Manipulations of MRR VGLUT3+ neurons did not impact spatial reference learning in SRM task, since no differences between the learning curves of the groups were observed. Chemogenetic manipulation resulted in no differences between the groups in short-term memory. However, 72h later, the control group showed the expected rise in latency, while excitatory group performed similarly as before and found the place of the platform significantly faster than controls. Optogenetic MRR-VGLUT3 stimulation had no such effects. However, the latency to find the platform increased significantly in the control group, but not in the excitatory group compared to the values of short-term memory. Conclusions:Our data showed a role of MRR-VGLUT3+ neurons in long-term memory formation for which long, extended excitation is required.

The medial prefrontal cortex (mPFC) plays a key role in coordinating novel but also previously acquired memories. However, how these memories are stored and maintained remains unclear. We addressed this question by using 1-photon calcium imaging of pyramidal cells in layer-V of the mPFC. We imaged the same set of cells over weeks in an olfaction guided working memory task. Mice were exposed to two different olfactory cues in the centre arm of an M-maze and trained to choose one of the side arms for reward collection. Once this association was learned, the calcium imaging started. First, we performed population imaging across 24 days in one consistent ('original') rule. A subset of cells was active on all recording days and showed stable spatial tuning over time. A decoder trained on neuronal activity from the first recording day could predict the animal's maze-position and trial outcome for each subsequent recording day. Secondly, we 'switched' the associated reward-location for the two olfactory cues. Animals needed substantial time to learn the new reward rule. However, the neuronal activity was similar to the one obtained during the 'original'-rule. Therefore, the animal's maze-position and trial outcome in the 'switched'-condition could be decoded based on neuronal activity collected in the 'original'-rule. We thus observed a stable cell-ensemble representing task-related spatial information, which is persistent across time and independent of rules and task-performance. Such a reliably active cell-ensemble could serve as a stable reference frame, helping the animal navigate in the context and allowing quick task-related decisions.

THE ROLE OF ASTROCYTIC GS-GPCR SIGNALING IN CORTICAL ENGRAM FORMATION AND REMOTE MEMORY RETRIEVAL

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Aline Mak, Michel Van Den Oever, Mark Verheijen
Vrije Universiteit Amsterdam, Center For Neurogenomics And Cognitive Research, Amsterdam, Netherlands

During learning, sparsely distributed neurons in the mPFC are activated and these specific neurons are required for remote memory retrieval, thereby forming an engram ensemble. Astrocytes and neuronal synaptic elements function together as bidirectional partners in the modulation of synaptic transmission, and interaction between these components likely has an important role in memory processing. However, little is known about the role of astrocytes, and in particular astrocytic Gs-GPCR signaling, in the encoding and retrieval of fear memory, as well as the associated formation and reactivation of an engram ensemble in the mPFC. Therefore, we aim to assess the role of astrocytic Gs-GPCR signaling in remote memory and cortical engram functioning using chemogenetic manipulation of cortical astrocytes during conditional fear conditioning (CFC). The Gs-coupled DREADD (rM3Ds) was specifically expressed in mPFC astrocytes to stimulate this pathway during fear memory encoding. Experiments were performed in a TRAP2-tdTomato transgenic mouse to permanently tag neurons that were active during CFC, and to determine their level of reactivation through co-localization with retrieval-induced c-Fos expression. Preliminary results indicate that stimulation of the Gs-GPCR pathway during CFC impaired subsequent remote memory expression and enhanced the size of the mPFC ensemble that was tagged during memory encoding. The relative reactivation rate of the tagged ensemble did not differ between rM3Ds and control mice. We tentatively conclude that activation of the astrocytic Gs-GPCR pathway in the mPFC during memory encoding increases the recruitment of neurons in a cortical engram ensemble, which negatively affects remote memory expression.

THE ROLE OF THE CA1 IN SOCIAL AND SPATIAL RECOGNITION MEMORY IN JUVENILE MALES AND FEMALES.

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Evleen Shehadeh, Mouna Maroun
University of Haifa, Sagol Department Of Neurobiology, Haifa, Israel

The hippocampus is involved in different types of learning and memory, including object location memory (OLM), and social recognition memory (SRM). Juvenility is a critical period for limbic system maturation, particularly of the medial prefrontal cortex and hippocampus, structures critical for OLM and SRM in adult animals. The neuroanatomical and behavioral development of juvenile males and females were assumed similar. However, our recent data show substantial differences in the role of prefrontal oxytocin (OXT) in pre-pubertal males and females (Maroun et al., 2020) in mediating extinction of fear for example. This study aims to examine whether the hippocampal sub-region CA1 has similar roles in mediating OLM and SRM in juvenile male and female rats. To that end, we microinjected either anisomycin (protein synthesis inhibitor) or OXT-receptor (OXTR) antagonist in the CA1 of juvenile male and female rats and examined both OLM and SRM. We found that anisomycin impairs the consolidation of long-term OLM in males, but not females. This differential effect seems also to be reflected in different expression of cFos, the neuronal activation marker, in the CA1 following the formation of OLM long-term memory. However, the SRM of both sexes was similarly hindered by anisomycin. Similar results were obtained with blockade of OXT receptors, which resulted in impaired OLM only in males and SRM impairment in both sexes. In conclusion, the data points to sex differences in mechanisms underlying OLM but not SRM within the developing CA1. These findings suggest a need for sex-specific approach to human developmental pathologies.

AIMS Breastmilk contains bioactive molecules essential for brain and cognitive development. Among the various components of human milk, sialylated human milk oligosaccharides (HMOs) have been proposed to be one of the key nutrients mediating the beneficial effects of breastfeeding on the offspring. We hypothesize that the reduced neonatal availability of the two main sialylated HMOs, 6'Sialyllactose (6'SL) and 3'Sialyllactose (3'SL), may impair attention, cognitive flexibility, and memory in adult mice. **METHODS** To modulate the concentrations of 6'SL and 3'SL only during lactation, we performed a cross-fostering design in which wild-type (WT) mice were reared by dams characterised by the absence of the genes synthesizing 6'SL and 3'SL knock-out (KO), producing milk without these sugars. We then tested the offspring for memory and attention in adulthood using T-maze and Barnes maze tests. **RESULTS** Compared to control mice, WT offspring deprived of 6'SL and 3'SL during lactation exhibited reduced memory and attentional capabilities. Specifically, WT mice reared to KO dams showed impaired working memory in the T-maze test and reduced spatial memory in the Barnes maze, and impairments in attentional capabilities in the attentional set-shifting task. **CONCLUSION** These results indicate that the absence of 6'SL and 3'SL in the neonatal period may impair the development of executive functions later in life. This study supports the hypothesis that early-life dietary sialylated HMOs exert a long-lasting role on the development of cognitive functions suggesting that their presence during the lactational stage may contribute to the development of the central nervous system.

Exposure to 3'Sialyllactose-Poor Milk during Lactation Impairs Cognitive Capabilities in Adulthood.
Breast milk exerts pivotal regulatory functions early in development whereby it contributes to the maturation of brain and associated cognitive functions. However, the specific components of maternal milk mediating this process have remained elusive. Sialylated human milk oligosaccharides (HMOs) represent likely candidates since they constitute the principal neonatal dietary source of sialic acid, which is crucial for brain development and neuronal patterning. We hypothesize that the selective neonatal lactational deprivation of a specific sialylated HMOs, sialyl(alpha2,3)lactose (3'SL), may impair cognitive capabilities (attention, cognitive flexibility, and memory) in adulthood in a preclinical model. To operationalize this hypothesis, we cross-fostered wild-type (WT) mouse pups to B6.129-/J dams, knock-out (KO) for the gene synthesizing 3'SL, thereby providing milk with approximately 80% 3'SL content reduction. We thus exposed lactating WT pups to a selective reduction of 3'SL and investigated multiple cognitive domains (including memory and attention) in adulthood. Furthermore, to account for the underlying electrophysiological correlates, we investigated hippocampal long-term potentiation (LTP). Neonatal access to 3'SL-poor milk resulted in decreased attention, spatial and working memory, and altered LTP compared to the control group. These results support the hypothesis that early-life dietary sialylated HMOs exert a long-lasting role in the development of cognitive functions.

Sialylated human milk oligosaccharides program cognitive development through a non-genomic transmission mode.
Breastmilk contains bioactive molecules essential for brain and cognitive development. While sialylated human milk

oligosaccharides (HMOs) have been implicated in phenotypic programming, their selective role and underlying mechanisms remained elusive. Here, we investigated the long-term consequences of a selective lactational deprivation of a specific sialylated HMO in mice. We capitalized on a knock-out (KO) mouse model (B6.129-St6gal1/J) lacking the gene responsible for the synthesis of sialyl(alpha2,6)lactose (6'SL), one of the two sources of sialic acid (Neu5Ac) to the lactating offspring. Neu5Ac is involved in the formation of brain structures sustaining cognition. To deprive lactating offspring of 6'SL, we cross-fostered newborn wild-type (WT) pups to KO dams, which provide 6'SL-deficient milk. To test whether lactational 6'SL deprivation affects cognitive capabilities in adulthood, we assessed attention, perseveration, and memory. To detail the associated endophenotypes, we investigated hippocampal electrophysiology, plasma metabolomics, and gut microbiota composition. To investigate the underlying molecular mechanisms, we assessed gene expression (at eye-opening and in adulthood) in two brain regions mediating executive functions and memory (hippocampus and prefrontal cortex, PFC). Compared to control mice, WT offspring deprived of 6'SL during lactation exhibited consistent alterations in all cognitive functions addressed, hippocampal electrophysiology, and in pathways regulating the serotonergic system (identified through gut microbiota and plasma metabolomics). These were associated with a site- (PFC) and time-specific (eye-opening) reduced expression of genes involved in central nervous system development. Our data suggest that 6'SL in maternal milk adjusts cognitive development through a short-term upregulation of genes modulating neuronal patterning in the PFC.

Genomic and physiological resilience in extreme environments are associated with a secure attachment style. Understanding individual capability to adjust to protracted confinement and isolation may inform adaptive plasticity and disease vulnerability/resilience, and may have long-term implications for operations requiring prolonged presence in distant and restricted environments. Individual coping depends on many different factors encompassing psychological dispositional traits, endocrine reactivity and their underlying molecular mechanisms (e.g. gene expression). A positive view of self and others (secure attachment style) has been proposed to promote individual resilience under extreme environmental conditions. Here, we tested this hypothesis and investigated the underlying molecular mechanisms in 13 healthy volunteers confined and isolated for 12 months in a research station located 1670 km away from the south geographic pole on the Antarctic Plateau at 3233 m above sea level. Study participants, stratified for attachment style, were characterised longitudinally (before, during and after confinement) for their psychological appraisal of the stressful nature of the expedition, diurnal fluctuations in endocrine stress reactivity, and gene expression profiling (transcriptomics). Predictably, a secure attachment style was associated with reduced psychological distress and endocrine vulnerability to stress. In addition, while prolonged confinement and isolation remarkably altered overall patterns of gene expression, such alteration was largely reduced in individuals characterised by a secure attachment style. Furthermore, increased resilience was associated with a reduced expression of genes involved in energy metabolism (mitochondrial function and oxidative phosphorylation). Ultimately, our data indicate that a secure attachment style may favour individual resilience in extreme environments and that such resilience can be mapped onto identifiable molecular substrates.

OVERWRITING AN INSTINCT: HOW INNATE CIRCUITRY CAN BE MODIFIED WITH EXPERIENCE

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Paul Conway[1], Antoine Harel[1], Andrea Muñoz Zamora[1], James O'Leary[1], Tomás Ryan[1,2,3,4]
[1]Trinity College Dublin, School Of Biochemistry And Immunology, Dublin, Ireland, [2]Trinity College Dublin, Trinity College Institute For Neuroscience, Dublin, Ireland, [3]Melbourne Brain Centre, University of Melbourne, Florey Institute Of Neuroscience And Mental Health, Melbourne, Australia, [4]Canadian Institute for Advanced Research (CIFAR), Child & Brain Development Program, Toronto, Canada

Behavioural neuroscience is implicitly divided into the study of innate behaviour (instincts) and learned behaviour (memory). However, it is becoming increasingly understood that instincts are not set in stone. Here, we use engram labelling strategies alongside optogenetics and chemogenetics to study the innate representation (*ingram*) of the instinctual response to visual looming stimuli, and understand how this ingram may change via learning. We used multiple training paradigms to alter behavioural responses to a visual looming or sweeping stimulus, including extinction, reinstatement, and counterconditioning. Our experiments demonstrate a remarkable plasticity of the innate looming/sweeping responses. We investigated how activity in the superior colliculus (SC) changes in response to these experiences by quantifying overlap of c-Fos expressing cells in the naïve and experienced behavioural states. We then manipulated SC activity using optogenetic and chemogenetic techniques and investigated the behavioural outcomes, demonstrating a strong defensive response to stimulation of the SC. This was further examined in the context of learning to determine how the activation of the SC post-extinction alters behaviour. We then considered the role of other brain regions using whole-brain histological analysis to identify new candidate regions that modulate innate and learned behavioural responses to looming stimuli. These findings indicate that the mouse visual looming response is highly plastic, and the complexity of this behaviour can only be explained by understanding the role of several regions, including but not limited to the SC. More broadly, we have demonstrated that instinctual representations in the brain communicate with neurons encoding learning.

COLD SENSITIVE ENGRAMS CONTROL WHOLE-BODY THERMOREGULATORY RESPONSES

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Andrea Muñoz Zamora[1,2], Aaron Douglas[1], Taylor Moniz[1,2], Lydia Marks[1,2], James O'Leary[1,2], Lydia Lynch[3], Tomás Ryan[1,2,4,5]
[1]Trinity College Dublin, School Of Biochemistry And Immunology, Dublin, Ireland, [2]Trinity College Dublin, Trinity College Institute Of Neuroscience, Dublin, Ireland, [3]Harvard Medical School, Brigham And Women's Hospital, Boston, United States of America, [4]University of Melbourne, Florey Institute Of Neuroscience And Mental Health, Melbourne, Australia, [5]Canadian Institute for Advanced Research, Child & Brain Development Program, Toronto, Canada

Maintenance of core body temperature within a narrow range is essential for physiological homeostasis, and for the survival of animals. When facing a thermal challenge such as a cold environment, the brain coordinates both autonomic and behavioral responses in order to maintain optimal body temperature. However, it is unknown how temperature information is precisely stored in the brain, and how it is converted into a whole-body physiological response. To investigate this, we conditioned animals to associate a particular context with a specific temperature, by combining thermoregulatory pavlovian conditioning with engram labelling technology and optogenetic approaches. We show that if mice are returned to an environment where they previously experienced a cold-challenge, they will increase their metabolic rates regardless of the actual environmental temperature. Moreover, mice develop a conditioned place aversion for the cold context, and avoid a cold environment if given the choice. In addition, we show that the hippocampus is highly activated during exposure to cold and when remembering the cold, indicating a potential key role for this structure during thermoregulation. Furthermore, we show that reactivating cold sensitive memory engrams in the hippocampus mimics the physiological responses seen during a cold-challenge. Together, our results show that remembering the cold is enough to cause whole-body autonomic and behavioral responses that enable an animal to maintain thermal homeostasis.

Propranolol Decreases Fear Expression by Modulating Fear Memory Traces.
Posttraumatic stress disorder can develop after a traumatic event and results in heightened, inappropriate fear and anxiety. Although approximately 8% of the U.S. population is affected by posttraumatic stress disorder, only two drugs have been approved by the Food and Drug Administration to treat it, both with limited efficacy. Propranolol, a nonselective β-adrenergic antagonist, has shown efficacy in decreasing exaggerated fear, and there has been renewed interest in using it to treat fear disorders.

Optogenetic reactivation of prefrontal social neural ensembles mimics social buffering of fear.
Social buffering occurs when the presence of a companion attenuates the physiological and/or behavioral effects of a stressful or fear-provoking event. It represents a way in which social interactions can immediately and potently modulate behavior. As such, social buffering is one mechanism by which strong social support increases resilience to mental illness. Although the behavioral and neuroendocrine impacts of social buffering are well studied in multiple species, including humans, the neuronal underpinnings of this behavioral phenomenon remain largely unexplored. Previous work has shown that the infralimbic prefrontal cortex (IL-PFC) is important for processing social information and, in separate studies, for modulating fear and anxiety. Thus, we hypothesized that socially active cells within the IL-PFC may integrate social information to modulate fear responsivity. To test this hypothesis, we employed social buffering paradigms in male and female mice. Similar to prior studies in rats, we found that the presence of a cagemate reduced freezing in fear- and anxiety-provoking contexts. In accordance with previous work, we demonstrated that interaction with a novel or familiar conspecific induces activity in the IL-PFC as evidenced by increased immediate early gene (IEG) expression. We then utilized an activity-dependent tagging murine line, the ArcCreER mice, to express channelrhodopsin (ChR2) in neurons active during the social encoding of a new cagemate. We found that optogenetic reactivation of these socially active neuronal ensembles

phenocopied the effects of cagemate presence in male and female mice in learned and innate fear contexts without being inherently rewarding or altering locomotion. These data suggest that a social neural ensemble within the IL-PFC may contribute to social buffering of fear. These neurons may represent a novel therapeutic target for fear and anxiety disorders.

Infantile amnesia, the developmental loss of memories formed in early childhood (prior to 2–4 years), affects all humans. Although behavioural neuroscientists have already demonstrated that rodents display infantile amnesia, little is known about the basic neurobiology of infantile amnesia and further its effect on memory engrams. We probe the question of how memories are stored in the brain throughout development by integrating engram labelling technology with mouse models of infantile amnesia. We show that infant mice demonstrate infantile amnesia for a range of behavioural paradigms including fear conditioning, novel object recognition and the Barnes maze. We successfully reactivated infant memories of various modalities in adult mice by optogenetically stimulating dentate gyrus engram cells that were labelled for a target experience during infancy. We used cell reactivation as a proxy of memory retrieval and demonstrate that the engram connectivity pattern survives infantile amnesia. Further, we were able to permanently reinstate lost infantile memories by artificially updating the memory engram and restoring natural access to the engram. Finally, we demonstrate that male, but not female, offspring from maternal immune activation (MIA) models do not experience infantile amnesia.

NATURAL FORGETTING AS A FORM OF ENGRAM CELL PLASTICITY

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

James O'Leary[1], Livia Autore[1], Eric Byrne[1], Rasmus Bruckner[2], Tomás Ryan[1,3,4,5]
[1]Trinity College Dublin, School Of Biochemistry And Immunology, Dublin, Ireland, [2]Freie Universität Berlin, Department Of Education And Psychology, Berlin, Germany, [3]Trinity College Dublin, Trinity College Institute Of Neuroscience, Dublin, Ireland, [4]University of Melbourne, Florey Institute Of Neuroscience And Mental Health, Melbourne, Australia, [5]Canadian Institute for Advanced Research, Child & Brain Development Program, Toronto, Canada

Memories are stored as ensembles of engram neurons and their successful recall involves reactivation of these cellular networks. While progress has been made in understanding the biology of engrams, there remain significant gaps in connecting these cell ensembles with the process of forgetting. We developed a forgetting paradigm based on an object recognition task and characterised the forgetting curve of wild-type mice. Under baseline conditions mice were able to recall an object memory 24 hrs post-training but exhibited no preference for the novel object after two weeks, indicating the initial memory was forgotten. Using engram labelling technology, active neurons within the dentate gyrus of c-fos-tTA transgenic mice were labelled during the initial encoding of an object memory. Mice that recalled the memory at 24 hrs showed a higher level of overlap between ChR2-EYFP+ and c-Fos+ cells, compared to mice that failed to recall the memory at two weeks, suggesting that the level of engram reactivation decreased as the memory was forgotten. Similarly, morphological analysis of engram cells indicated that spine density decreased with the level of forgetting and engram activation. Furthermore, optogenetic reactivation of dentate gyrus engram cells facilitated the recall of a previously forgotten object memory. Finally, the inhibition of Rac1 protein prevented forgetting, while its activation following memory encoding accelerated forgetting. Together, these findings suggest that forgetting is an adaptive form of engram plasticity that involves circuit remodeling, that allows engrams to switch from an accessible state to an inaccessible state.

Chronic interleukin-1β in the dorsal hippocampus impairs behavioural pattern separation.
Understanding the long-term consequences of chronic inflammation in the hippocampus may help to develop therapeutic targets for the treatment of cognitive disorders related to stress, ageing and neurodegeneration. The hippocampus is particularly vulnerable to increases in the pro-inflammatory cytokine interleukin-1β (IL-1β), a mediator of neuroinflammation, with elevated levels implicated in the aetiology of neurodegenerative diseases such as Alzheimer's and Parkinson's, and in stress-related disorders such as depression. Acute increases in hippocampal IL-1β have been shown to impair cognition and reduce adult hippocampal neurogenesis, the birth of new neurons. However, the impact of prolonged increases in IL-1β, as evident in clinical conditions, on cognition has not been fully explored. Therefore, the present study utilized a lentiviral approach to induce long-term overexpression of IL-1β in the dorsal hippocampus of adult male Sprague Dawley rats and examine its impact on cognition. Following three weeks of viral integration, pattern separation, a process involving hippocampal neurogenesis, was impaired in IL-1β-treated rats in both object-location and touchscreen operant paradigms. This was coupled with a decrease in the number and neurite complexity of immature neurons in the hippocampus. Conversely, tasks involving the hippocampus, but not sensitive to disruption of hippocampal neurogenesis, including spontaneous alternation, novel object and location recognition were unaffected. Touchscreen operant visual discrimination, a cognitive task involving the prefrontal cortex, was largely unaffected by IL-1β overexpression. In conclusion, these findings suggest that chronically elevated IL-1β in the hippocampus selectively impairs pattern separation. Inflammatory-mediated disruption of adult hippocampal neurogenesis may contribute to the cognitive decline associated with neurodegenerative and stress-related disorders.

Chronic intrahippocampal interleukin-1β overexpression in adolescence impairs hippocampal neurogenesis but not neurogenesis-associated cognition.
Both neuroinflammation and adult hippocampal neurogenesis (AHN) are implicated in many neurodegenerative disorders as

well as in neuropsychiatric disorders, which often become symptomatic during adolescence. A better knowledge of the impact that chronic neuroinflammation has on the hippocampus during the adolescent period could lead to the discovery of new therapeutics for some of these disorders. The hippocampus is particularly vulnerable to altered concentrations of the pro-inflammatory cytokine interleukin-1β (IL-1β), with elevated levels implicated in the aetiology of neurodegenerative disorders such as Alzheimer's and Parkinson's, and stress-related disorders such as depression. The effect of acutely and chronically elevated concentrations of hippocampal IL-1β have been shown to reduce AHN in adult rodents. However, the effect of exposure to chronic overexpression of hippocampal IL-1β during adolescence, a time of increased vulnerability, hasn't been fully interrogated. Thus, in this study we utilized a lentiviral approach to induce chronic overexpression of IL-1β in the dorsal hippocampus of adolescent male Sprague Dawley rats for 5 weeks, during which time its impact on cognition and hippocampal neurogenesis were examined. A reduction in hippocampal neurogenesis was observed along with a reduced level of neurite branching on hippocampal neurons. However, there was no effect of IL-1β overexpression on performance in pattern separation, novel object recognition or spontaneous alternation in the Y maze. Our study has highlighted that chronic IL-1β overexpression in the hippocampus during the adolescent period exerts a negative impact on neurogenesis independent of cognitive performance, and suggests a degree of resilience of the adolescent hippocampus to inflammatory insult.

Differential effects of adolescent and adult-initiated exercise on cognition and hippocampal neurogenesis.
Adolescence is a critical period for postnatal brain maturation and thus a time when environmental influences may affect cognitive processes in later life. Exercise during adulthood has been shown to increase hippocampal neurogenesis and enhance cognition. However, the impact of exercise initiated in adolescence on the brain and behavior in adulthood is not fully understood. The aim of this study was to compare the impact of voluntary exercise that is initiated during adolescence or early adulthood on cognitive performance in hippocampal-dependent and -independent processes using both object-based and touchscreen operant paradigms. Adult (8 week) and adolescent (4 week) male Sprague-Dawley rats had access to a running wheel (exercise) or were left undisturbed (sedentary control) for 4 weeks prior to behavioral testing and for the duration of the experiment. Results from touchscreen-based tasks showed that reversal learning was enhanced by both adult and adolescent-initiated exercise, while only exercise that began in adolescence induced a subtle but transient increase in performance on a location discrimination task. Spontaneous alternation in the Y-maze was impaired following adolescent onset exercise, while object memory was unaffected by either adult or adolescent-initiated exercise. Adolescent-initiated exercise increased the number of hippocampal DCX cells, an indicator of neurogenesis. It also promoted the complexity of neurites on DCX cells, a key process for synaptic integration, to a greater degree than adult-initiated exercise. Together the data here show that exercise during the adolescent period compared to adulthood differentially affects cognitive processes and the development of new hippocampal neurons in later life.

Differential effects of adolescent and adult-initiated voluntary exercise on context and cued fear conditioning.
Adolescence is a critical period for postnatal brain maturation and a time during which there is increased susceptibility to developing emotional and cognitive-related disorders. Exercise during adulthood has been shown to increase hippocampal plasticity and enhance cognition. However, the impact of exercise initiated in adolescence, on brain and behaviour in adulthood is not yet fully explored or understood. The aim of this study was to compare the impact of voluntary exercise that was initiated either during adolescence or early adulthood on cognitive performance in hippocampal and amygdala-dependent fear conditioning tasks in adulthood. Adult (eight weeks old) and adolescent (four weeks old) male Sprague Dawley rats had access to a running wheel (exercise) or were left undisturbed (sedentary control) for seven weeks. Adult-initiated exercise enhanced both contextual and cued fear conditioning, while conversely, exercise that began in adolescence did not affect performance in these tasks. These behaviours were accompanied by differential expression of plasticity-related genes in the hippocampus and amygdala in adulthood. Specifically, adolescent-initiated exercise increased the expression of an array of plasticity related genes in the hippocampus including BDNF, synaptophysin, Creb, PSD-95, Arc, TLX and DCX, while adult-initiated exercise did not affect hippocampal plasticity related genes. Together results show that exercise initiated during adolescence has a differential effect on hippocampal and amygdala-dependent behaviour and neuronal plasticity compared to when exercise was initiated in adulthood. These findings reinforce adolescence as a period during which environmental influences have a distinct impact on neuronal plasticity and cognition. This article is part of the Special Issue entitled "Neurobiology of Environmental Enrichment".

A low-cost touchscreen operant chamber using a Raspberry Pi™.

The development of a touchscreen platform for rodent testing has allowed new methods for cognitive testing that have been back-translated from clinical assessment tools to preclinical animal models. This platform for cognitive assessment in animals is comparable to human neuropsychological tests such as those employed by the Cambridge Neuropsychological Test Automated Battery, and thus has several advantages compared to the standard maze apparatuses typically employed in rodent behavioral testing, such as the Morris water maze. These include improved translation of preclinical models, as well as high throughput and the automation of animal testing. However, these systems are relatively expensive, which can impede progress for researchers with limited resources. Here we describe a low-cost touchscreen operant chamber based on the single-board computer, Raspberry Pi, which is capable of performing tasks similar to those supported by current state-of-the-art systems. This system provides an affordable alternative for cognitive testing in a touchscreen operant paradigm for researchers with limited funding.

The nuclear receptor Tlx regulates motor, cognitive and anxiety-related behaviours during adolescence and adulthood.
The nuclear receptor Tlx is a key regulator of embryonic and adult hippocampal neurogenesis and has been genetically linked to bipolar disorder. Mice lacking Tlx (Nr2e1(-/-)) display deficits in adult hippocampal neurogenesis and behavioural abnormalities. However, whether Tlx regulates behaviour during adolescence or in a sex-dependent manner remains unexplored. Therefore, we investigated the role of Tlx in a series of behavioural tasks in adolescent male and female mice with a spontaneous deletion of Tlx (Nr2e1(-/-) mice). Testing commenced at adolescence (postnatal day 28) and continued until adulthood (postnatal day 67). Adolescent male and female Nr2e1(-/-) mice were hyperactive in an open field, an effect that persisted in adulthood. Male but not female Nr2e1(-/-) mice exhibited reduced thigmotaxis during adolescence and adulthood. Impairments in rotarod motor performance developed in male and female Nr2e1(-/-) mice at the onset of adulthood. Spontaneous alternation in the Y-maze, a hippocampus-dependent task, was impaired in adolescent but not adult male and female Nr2e1(-/-) mice. Contextual fear conditioning was impaired in adolescent male Nr2e1(-/-) mice only, but both male and female adolescent Nr2e1(-/-) mice showed impaired cued fear conditioning, a hippocampal-amygdala dependent cognitive process. These deficits persisted into adulthood in males but not females. In conclusion, deletion of Tlx impairs motor, cognitive and anxiety-related behaviours during adolescence and adulthood in male and female mice with most effects occurring during adolescence rather than adulthood, independent of housing conditions. This suggests that Tlx has functions beyond regulation of adult hippocampal neurogenesis, and may be an important target in understanding neurobiological disorders.

Regulation of behaviour by the nuclear receptor TLX.
The orphan nuclear receptor Tlx (Nr2e1) is a key regulator of both embryonic and adult hippocampal neurogenesis. Several different mouse models have been developed which target Tlx in vivo including spontaneous deletion models (from birth) and targeted and conditional knockouts. Although some conflicting findings have been reported, for the most part studies have demonstrated that Tlx is important in regulating processes that underlie neurogenesis, spatial learning, anxiety-like behaviour and interestingly, aggression. More recent data have demonstrated that disrupting Tlx during early life induces hyperactivity and that Tlx plays a role in emotional regulation. Moreover, there are sex- and age-related differences in some behaviours in Tlx knockout mice during adolescence and adulthood. Here, we discuss the role of Tlx in motor-, cognitive-, aggressive- and anxiety-related behaviours during adolescence and adulthood. We examine current evidence which provides insight into Tlx during neurodevelopment, and offer our thoughts on the function of Tlx in brain and behaviour. We further hypothesize that Tlx is a key target in understanding the emergence of neurobiological disorders during adolescence and early adulthood.

CONNECTING THE ENGRAM DOTS: ROLE OF CONNECTIVITY IN MEMORY FORMATION

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Engram cells are a subset of neurons that experience plasticity during learning, allowing them to store long-term memory information. The connectivity pattern between these 'building blocks' of memory has been proposed as a candidate mechanism through which to hold the information in a stable state. However, the mechanisms of the formation and maintenance of engram cell connectivity are poorly understood. We combine inducible Cre recombinase-dependent labeling and doxycycline controlled tTA/TRE system to achieve simultaneous engram labeling of two experiences that are either separated or become associated by natural learning. The association of the memories induces a physical link between the previously-separated engrams, across the monosynaptic connection ventral CA1 to amygdala, indicating that learning translates perceptual information from the outside into a change in the connectivity pattern between engram cells. We further explore how this change in the connectivity pattern is required for the memory to be expressed, by optogenetically silencing the reactivation of the second engram. Finally, we explore the molecular correlates of the association and describe the modulation of plasticity-related mechanisms as a consequence of the connectivity pattern change. Overall, our research supports that learning experiences translate the information from the outside into the connectivity pattern between engram cells.

Non-productive angiogenesis disassembles Aß plaque-associated blood vessels.
The human Alzheimer's disease (AD) brain accumulates angiogenic markers but paradoxically, the cerebral microvasculature is reduced around Aß plaques. Here we demonstrate that angiogenesis is started near Aß plaques in both AD mouse models and human AD samples. However, endothelial cells express the molecular signature of non-productive angiogenesis (NPA) and accumulate, around Aß plaques, a tip cell marker and IB4 reactive vascular anomalies with reduced NOTCH activity. Notably, NPA induction by endothelial loss of presenilin, whose mutations cause familial AD and which activity has been shown to decrease with age, produced a similar vascular phenotype in the absence of Aß pathology. We also show that Aß plaque-associated NPA locally disassembles blood vessels, leaving behind vascular scars, and that microglial phagocytosis contributes to the local loss of endothelial cells. These results define the role of NPA and microglia in local blood vessel disassembly and highlight the vascular component of presenilin loss of function in AD.

Engram cell connectivity: an evolving substrate for information storage.
Understanding memory requires an explanation for how information can be stored in the brain in a stable state. The change in the brain that accounts for a given memory is referred to as an engram. In recent years, the term engram has been operationalized as the cells that are activated by a learning experience, undergoes plasticity, and are sufficient and necessary for memory recall. Using this framework, and a growing toolbox of related experimental techniques, engram manipulation has become a central topic in behavioral, systems, and molecular neuroscience. Recent research on the topic has provided novel insights into the mechanisms of long-term memory storage, and its overlap with instinct. We propose that memory and instinct may be embodied as isomorphic topological structures within the brain's microanatomical circuitry.

Substantia nigra dopaminergic neurons and striatal interneurons are engaged in three parallel but interdependent postnatal neurotrophic circuits.
The striatum integrates motor behavior using a well-defined microcircuit whose individual components are independently affected in several neurological diseases. The glial cell line-derived neurotrophic factor (GDNF), synthesized by striatal interneurons, and Sonic hedgehog (Shh), produced by the dopaminergic neurons of the substantia nigra (DA SNpc), are both involved in the nigrostriatal maintenance but the reciprocal neurotrophic relationships among these neurons are only partially understood. To define the postnatal neurotrophic connections among fast-spiking GABAergic interneurons (FS), cholinergic interneurons (ACh), and DA SNpc, we used a genetically induced mouse model of postnatal DA SNpc neurodegeneration and separately eliminated Smoothened (Smo), the obligatory transducer of Shh signaling, in striatal interneurons. We show that FS postnatal survival relies on DA SNpc and is independent of Shh signaling. On the contrary, Shh signaling but not dopaminergic striatal innervation is required to maintain ACh in the postnatal striatum. ACh are required for DA SNpc survival in a GDNF-independent manner. These data demonstrate the existence of three parallel but interdependent neurotrophic relationships between SN and striatal interneurons, partially defined by Shh and GDNF. The definition of these new neurotrophic interactions opens the search for new molecules involved in the striatal modulatory circuit maintenance with potential therapeutic value.

United states of amnesia: rescuing memory loss from diverse conditions.
Amnesia - the loss of memory function - is often the earliest and most persistent symptom of dementia. It occurs as a consequence of a variety of diseases and injuries. These include neurodegenerative, neurological or immune disorders, drug abuse, stroke or head injuries. It has both troubled and fascinated humanity. Philosophers, scientists, physicians and anatomists have all pursued an understanding of how we learn and memorise, and why we forget. In the last few years, the development of memory engram labelling technology has greatly impacted how we can experimentally study memory and its disorders in animals. Here, we present a concise discussion of what we have learned about amnesia through the manipulation of engrams, and how we may use this knowledge to inform novel treatments of amnesia.

Simultaneous Detection of Both GDNF and GFRα1 Expression Patterns in the Mouse Central Nervous System.
Glial cell line-derived neurotrophic factor (GDNF) is proposed as a therapeutic tool in Parkinson's disease, addiction-related disorders, and neurodegenerative conditions affecting motor neurons (MNs). Despite the high amount of work about GDNF therapeutic application, the neuronal circuits requiring GDNF trophic support in the brain and spinal cord (SC) are poorly characterized. Here, we defined GDNF and GDNF family receptor-α 1 (GFRα1) expression pattern in the brain and SC of newborn and adult mice. We performed systematic and simultaneous detection of EGFP and LacZ expressing alleles in reporter mice and asked whether modifications of this signaling pathway lead to a significant central nervous system (CNS) alteration. GFRα1 was predominantly expressed by neurons but also by an unexpected population of non-neuronal cells. GFRα1 expression pattern was wider in neonatal than in adult CNS and GDNF expression was restricted in comparison with GFRα1 at both developmental time points. The use of confocal microscopy to imaging X-gal deposits and EGFP allowed us to identify regions containing cells that expressed both proteins and to discriminate between auto and non-autotrophic signaling. We also suggested long-range GDNF-GFRα1 circuits taking advantage of the ability of the EGFP genetically encoded reporter to label long distance projecting axons. The complete elimination of either the ligand or the receptor during development did not produce major abnormalities, suggesting a preponderant role for GDNF signaling during adulthood. In the SC, our results pointed to local modulatory interneurons as the main target of GDNF produced by Clarke's column (CC) cells. Our work increases the understanding on how GDNF signals in the CNS and establish a crucial framework for posterior studies addressing either the biological role of GDNF or the optimization of trophic factor-based therapies.

INTERFERING WITH ENGRAM RETRIEVAL: THE NEUROBIOLOGY OF FORGETTING

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Livia Autore[1], James O'Leary[1], Clara Ortega-De San Luis[1], Rasmus Bruckner[2], Tomás Ryan[1,3,4,5]
[1]Trinity College Dublin, School Of Biochemistry And Immunology, Dublin, Ireland, [2]Freie Universität Berlin, Department Of Education And Psychology, Berlin, Germany, [3]Trinity College Dublin, Trinity College Institute For Neuroscience, Dublin, Ireland, [4]University of Melbourne, Florey Institute Of Neuroscience And Mental Health, Melbourne, Australia, [5]Canadian Institute for Advanced Research (CIFAR), Child & Brain Development Program, Toronto, Canada

While investigation of engram cell properties and functionality during memory formation and recall has been extensive, less is known about how engram cells are affected by forgetting. We sought to elucidate the behavioural and neurobiological correlates of retroactive interference. We characterized a form of interference-based forgetting using an object memory behavioural paradigm. Using this behaviour, we labelled dentate gyrus (DG) engram cells in mice during object exposure, and studied the effect of retroactive interference on engram cell function, showing that interference results in decreased engram cell reactivation during recall trials. We found that, following interference, a brief re-exposure to the original stimulus is sufficient to restore access to the missing information evidenced by reactivation of the originally labelled ensemble. Moreover, exposure to a misleading cue drives the reconsolidation of a ‘false’ memory. Furthermore, through optogenetic stimulation of engram cells we were able to elicit the artificial retrieval of the forgotten memory. Together, these findings indicate that retroactive interference modulates the accessibility of engram cells in a manner that is both reversible and updatable. Retroactive interference may constitute a form of adaptive forgetting, where in everyday life new perceptual and environmental inputs modulate the natural forgetting process.

Offline ventral subiculum-ventral striatum serial communication is required for spatial memory consolidation.
The hippocampal formation is considered essential for spatial navigation. In particular, subicular projections have been suggested to carry spatial information from the hippocampus to the ventral striatum. However, possible cross-structural communication between these two brain regions in memory formation has thus far been unknown. By selectively silencing the subiculum-ventral striatum pathway we found that its activity after learning is crucial for spatial memory consolidation and learning-induced plasticity. These results provide new insight into the neural circuits underlying memory consolidation and establish a critical role for off-line cross-regional communication between hippocampus and ventral striatum to promote the storage of complex information.

A FEAR MEMORY ENGRAM IN THE MOUSE AUDITORY CORTEX

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Marius Rosier[1,2], George Stuyt[1], Luca Godenzini[1], Tomás Ryan[1,2,3,4], Lucy Palmer[1]
[1]University of Melbourne, Florey Institute Of Neuroscience, Parkville, Australia, [2]Trinity College Dublin, Trinity College Institute Of Neuroscience, Dublin, Ireland, [3]Trinity College Dublin, School Of Biochemistry And Immunology, Dublin, Ireland, [4]Canadian Institute for Advanced Research, Child & Brain Development Program, Toronto, Canada

Memory is supported by ensembles of neurons known as engram cells. While engram cells have been well characterized in the hippocampus and related brain regions, little is known about the cellular properties of engram cells in sensory cortical areas. This study used activity-dependant engram tagging technology and patch clamp electrophysiology to characterize the cellular and dendritic properties of engram cells within the auditory cortex. Using tone fear conditioning and optogenetics in c-fos-tTA transgenic mice, we identified a population of engram cells with specific properties amongst layer 5 pyramidal cells. Using histological methods, we showed that these engram cells are reactivated by natural recall. Furthermore, their optogenetic reactivation induced behavioural expression of fear memory. *Ex vivo* electrophysiological recordings showed that photoactivation of engram cell axons elicited a stronger synaptic response in engram cells than in non-engram cells, suggesting the formation of a local engram network within the auditory cortex after learning. Analysis of the cellular intrinsic properties revealed that Ih currents, key regulators of dendritic excitability, are increased in engram cells compared to non-engram cells, suggesting a learning-induced plasticity of dendritic excitability. In conclusion, we identified and characterised a population of engram cells forming a local engram network with specific intrinsic properties, that manifest at the dendritic level through regulation of Ih currents.

Post-learning paradoxical sleep deprivation impairs reorganization of limbic and cortical networks associated with consolidation of remote contextual fear memory in mice.
Paradoxical sleep (PS) has been shown to play an important role in memory, in particular in emotional memory processes. However, the involvement of this particular sleep stage in the systemic consolidation of remote (30 days old) memory has never been tested. We examined whether post-learning PS could play a role in the consolidation of remote fearful memory and in the brain network reorganization that depends on it.

IMPAIRED PATTERN COMPLETION DURING MEMORY RECALL IN A MOUSE MODEL OF FRAGILE X SYNDROME

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Caroline Zeitouny[1], Martin Korte[1,2], Kristin Michaelsen-Preusse[1]
[1]TU Braunschweig, Department Of Cellular Neurobiology, Zoological Institute, Braunschweig, Germany, [2]Helmholtz Center for Infection Research, Neuroinflammation And Neurodegeneration Group, Braunschweig, Germany

The Fragile X Syndrome (FXS) is the leading monogenetic cause of cognitive impairment and autism. FXS symptoms include excessive adherence to patterns indicating perturbed hippocampal networks. The hippocampus is involved in pattern separation/completion processes during memory formation. Especially the CA3 region is of interest because of its auto-associative recurrent inputs. The absence of the fragile X mental retardation protein (FMRP) in patients and Fmr1 KO mice leads to an abnormal development of dendritic spines which form the postsynaptic compartment. Recently, we showed that different synapse types on CA3 neurons are affected differently by the absence of FMRP. While mossy fiber inputs to CA3 neurons are transiently premature during the fourth postnatal week, collateral/commissural inputs onto regular spines are increased in number in adult animals. Therefore, we were interested whether this would result in specific impairments in information processing in CA3 neurons. The CA3 region plays a pivotal role in pattern completion processes important for efficient memory recall even from parts of the initial memory stimulus. We therefore subjected Fmr1 mice to spatial training in the Morris water maze task and performed partially cued probe trials by selectively removing spatial cues. Consistent with the collateral spine phenotype observed in adult animals, we can show an impairment in pattern completion in adult and not in juvenile animals. Future experiments are needed to reveal whether the spine phenotype could be restored using regular spatial training or an enriched environment to tune hippocampal networks and whether this would restore pattern completion in the hippocampus.

STUDYING THE ROLE OF CB1 RECEPTORS ON MEMORY AND NAVIGATION IN MALE AND FEMALE MICE

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Jon Egaña-Huguet, Lucia Sangroniz-Beltran, Aitor Aranguren-Alberdi, Otadi Aguirrebengoa, Maria Vella, Itziar Bonilla Del Río, Nagore Puente, Pedro Grandes, Edgar Soria-Gomez

Hippocampal circuits play a crucial role in cognitive processes (e.g., navigation strategies). Furthermore, cortical areas participate in decision-making and emotional processes shaping the performance of the animals during memory tasks. In this work, we want to dissect the specific and sex-dependent role of CB1 signaling in different circuits on memory and navigation. Methods: We use behavioral genetics and pharmacology in C57BL6 and CB1-flox male and female mice carrying a Cre-mediated CB1 deletion. Viral vectors (AAV-Cre) were injected into the hippocampus and the prefrontal cortex. We use the Barnes maze test to assess cognitive performance (e.g., memory, navigation). Furthermore, a battery of anxiety-like behavioral protocols is performed prior to cognitive evaluation to rule out potential confounding factors. Results: intraperitoneal injection of THC immediately after each day of acquisition in the Barnes maze impairs memory consolidation in males but not in females. Interestingly, THC-treated mice specifically show a decrease in spatial strategy, suggesting a direct effect of the pharmacological treatment on hippocampal circuits. On the other hand, male and female CB1-flox mice carrying a hippocampal or prefrontal CB1 deletion present no significant changes in the learning processes compared to control littermates. However, CB1 deletion on male mice produced a specific decrease in the spatial strategy. Strikingly, such changes were not found on female mice. Conclusions: These results show that CB1 receptors in the hippocampus and the prefrontal cortex are necessary for developing and consolidating navigation strategies in a sex-dependent way.

The Endocannabinoid System in Glial Cells and Their Profitable Interactions to Treat Epilepsy: Evidence from Animal Models.
Epilepsy is one of the most common neurological conditions. Yearly, five million people are diagnosed with epileptic-related disorders. The neuroprotective and therapeutic effect of (endo)cannabinoid compounds has been extensively investigated in several models of epilepsy. Therefore, the study of specific cell-type-dependent mechanisms underlying cannabinoid effects is crucial to understanding epileptic disorders. It is estimated that about 100 billion neurons and a roughly equal number of glial cells co-exist in the human brain. The glial population is in charge of neuronal viability, and therefore, their participation in brain pathophysiology is crucial. Furthermore, glial malfunctioning occurs in a wide range of neurological disorders. However, little is known about the impact of the endocannabinoid system (ECS) regulation over glial cells, even less in pathological conditions such as epilepsy. In this review, we aim to compile the existing knowledge on the role of the ECS in different cell types, with a particular emphasis on glial cells and their impact on epilepsy. Thus, we propose that glial cells could be a novel target for cannabinoid agents for treating the etiology of epilepsy and managing seizure-like disorders.

Environmental Enrichment Rescues Endocannabinoid-Dependent Synaptic Plasticity Lost in Young Adult Male Mice after Ethanol Exposure during Adolescence.
Binge drinking (BD) is a serious health concern in adolescents as high ethanol (EtOH) consumption can have cognitive sequelae later in life. Remarkably, an enriched environment (EE) in adulthood significantly recovers memory in mice after adolescent BD, and the endocannabinoid, 2-arachydonoyl-glycerol (2-AG), rescues synaptic plasticity and memory impaired in adult rodents upon adolescent EtOH intake. However, the mechanisms by which EE improves memory are unknown. We investigated this in adolescent male C57BL/6J mice exposed to a drinking in the dark (DID) procedure four days per week for a duration of 4 weeks. After DID, the mice were nurtured under an EE for 2 weeks and were subjected to the Barnes Maze Test performed the last 5 days of withdrawal. The EE rescued memory and restored the EtOH-disrupted endocannabinoid (eCB)-dependent excitatory long-term depression at the dentate medial perforant path synapses (MPP-LTD). This recovery was dependent on both the cannabinoid CB1 receptor and group I metabotropic glutamate receptors (mGluRs) and required

2-AG. Also, the EE had a positive effect on mice exposed to water through the transient receptor potential vanilloid 1 (TRPV1) and anandamide (AEA)-dependent MPP long-term potentiation (MPP-LTP). Taken together, EE positively impacts different forms of excitatory synaptic plasticity in water- and EtOH-exposed brains.

Lack of the Transient Receptor Potential Vanilloid 1 Shifts Cannabinoid-Dependent Excitatory Synaptic Plasticity in the Dentate Gyrus of the Mouse Brain Hippocampus.
The transient receptor potential vanilloid 1 (TRPV1) participates in synaptic functions in the brain. In the dentate gyrus, post-synaptic TRPV1 in the granule cell (GC) dendritic spines mediates a type of long-term depression (LTD) of the excitatory medial perforant path (MPP) synapses independent of pre-synaptic cannabinoid CB receptors. As CB receptors also mediate LTD at these synapses, both CB and TRPV1 might be influencing the activity of each other acting from opposite synaptic sites. We tested this hypothesis in the MPP-GC synapses of mice lacking TRPV1 (TRPV1-/-). Unlike wild-type (WT) mice, low-frequency stimulation (10 min at 10 Hz) of TRPV1-/- MPP fibers elicited a form of long-term potentiation (LTP) that was dependent on (1) CB receptors, (2) the endocannabinoid 2-arachidonoylglycerol (2-AG), (3) rearrangement of actin filaments, and (4) nitric oxide signaling. These functional changes were associated with an increase in the maximum binding efficacy of guanosine-5'-O-(3-[S]thiotriphosphate) ([S]GTPγS) stimulated by the CB receptor agonist CP 55,940, and a significant decrease in receptor basal activation in the TRPV1-/- hippocampus. Finally, TRPV1-/- hippocampal synaptosomes showed an augmented level of the guanine nucleotide-binding (G) Gα, Gα, and Gα protein alpha subunits. Altogether, the lack of TRPV1 modifies CB receptor signaling in the dentate gyrus and causes the shift from CB receptor-mediated LTD to LTP at the MPP-GC synapses.

33692673: Egaña-Huguet J, Bonilla-Del Río I, Gómez-Urquijo SM, Mimenza A, Saumell-Esnaola M, Borrega-Roman L, García Del Caño G, Sallés J, Puente N, Gerrikagoitia I, Elezgarai I, Grandes P
The Absence of the Transient Receptor Potential Vanilloid 1 Directly Impacts on the Expression and Localization of the Endocannabinoid System in the Mouse Hippocampus.
The transient receptor potential vanilloid 1 (TRPV1) is a non-selective ligand-gated cation channel involved in synaptic transmission, plasticity, and brain pathology. In the hippocampal dentate gyrus, TRPV1 localizes to dendritic spines and dendrites postsynaptic to excitatory synapses in the molecular layer (ML). At these same synapses, the cannabinoid CB receptor (CBR) activated by exogenous and endogenous cannabinoids localizes to the presynaptic terminals. Hence, as both receptors are activated by endogenous anandamide, co-localize, and mediate long-term depression of the excitatory synaptic transmission at the medial perforant path (MPP) excitatory synapses though by different mechanisms, it is plausible that they might be exerting a reciprocal influence from their opposite synaptic sites. In this anatomical scenario, we tested whether the absence of TRPV1 affects the endocannabinoid system. The results obtained using biochemical techniques and immunoelectron microscopy in a mouse with the genetic deletion of TRPV1 show that the expression and localization of components of the endocannabinoid system, included CBR, change upon the constitutive absence of TRPV1. Thus, the expression of fatty acid amide hydrolase (FAAH) and monoacylglycerol lipase (MAGL) drastically increased in TRPV1 whole homogenates. Furthermore, CBR and MAGL decreased and the cannabinoid receptor interacting protein 1a (CRIP1a) increased in TRPV1 synaptosomes. Also, CBR positive excitatory terminals increased, the number of excitatory terminals decreased, and CBR particles dropped significantly in inhibitory terminals in the dentate ML of TRPV1 mice. In the outer 2/3 ML of the TRPV1 mutants, the proportion of CBR particles decreased in dendrites, and increased in excitatory terminals and astrocytes. In the inner 1/3 ML, the proportion of labeling increased in excitatory terminals, neuronal mitochondria, and dendrites. Altogether, these observations indicate the existence of compensatory changes in the endocannabinoid system upon TRPV1 removal, and endorse the importance of the potential functional adaptations derived from the lack of TRPV1 in the mouse brain.

31022405: Peñasco S, Rico-Barrio I, Puente N, Gómez-Urquijo SM, Fontaine CJ, Egaña-Huguet J, Achicallende S, Ramos A, Reguero L, Elezgarai I, Nahirney PC, Christie BR, Grandes P
Endocannabinoid long-term depression revealed at medial perforant path excitatory synapses in the dentate gyrus.
The endocannabinoid system modulates synaptic plasticity in the hippocampus, but a link between long-term synaptic plasticity and the type 1 cannabinoid (CB) receptor at medial perforant path (MPP) synapses remains elusive. Here, immuno-electron microscopy in adult mice showed that ~26% of the excitatory synaptic terminals in the middle 1/3 of the dentate molecular layer (DML) contained CB receptors, and field excitatory postsynaptic potentials evoked by MPP stimulation were inhibited by CB receptor activation. In addition, MPP stimulation at 10 Hz for 10 min triggered CB receptor-dependent excitatory long-term depression (eCB-eLTD) at MPP synapses of wild-type mice but not on CB-knockout mice. This eCB-

eLTD was group I mGluR-dependent, required intracellular calcium influx and 2-arachydonoyl-glycerol (2-AG) synthesis but did not depend on N-methyl-d-aspartate (NMDA) receptors. Overall, these results point to a functional role for CB receptors with eCB-eLTD at DML MPP synapses and further involve these receptors in memory processing within the adult brain.

29480581: Gutiérrez-Rodríguez A, Bonilla-Del Río I, Puente N, Gómez-Urquijo SM, Fontaine CJ, Egaña-Huguet J, Elezgarai I, Ruehle S, Lutz B, Robin LM, Soria-Gómez E, Bellocchio L, Padwal JD, van der Stelt M, Mendizabal-Zubiaga J, Reguero L, Ramos A, Gerrikagoitia I, Marsicano G, Grandes P

Localization of the cannabinoid type-1 receptor in subcellular astrocyte compartments of mutant mouse hippocampus.
Astroglial type-1 cannabinoid (CB) receptors are involved in synaptic transmission, plasticity and behavior by interfering with the so-called tripartite synapse formed by pre- and post-synaptic neuronal elements and surrounding astrocyte processes. However, little is known concerning the subcellular distribution of astroglial CB receptors. In particular, brain CB receptors are mostly localized at cells' plasmalemma, but recent evidence indicates their functional presence in mitochondrial membranes. Whether CB receptors are present in astroglial mitochondria has remained unknown. To investigate this issue, we included conditional knock-out mice lacking astroglial CB receptor expression specifically in glial fibrillary acidic protein (GFAP)-containing astrocytes (GFAP-CB -KO mice) and also generated genetic rescue mice to re-express CB receptors exclusively in astrocytes (GFAP-CB -RS). To better identify astroglial structures by immunoelectron microscopy, global CB knock-out (CB -KO) mice and wild-type (CB -WT) littermates were intra-hippocampally injected with an adeno-associated virus expressing humanized renilla green fluorescent protein (hrGFP) under the control of human GFAP promoter to generate GFAPhrGFP-CB -KO and -WT mice, respectively. Furthermore, double immunogold (for CB) and immunoperoxidase (for GFAP or hrGFP) revealed that CB receptors are present in astroglial mitochondria from different hippocampal regions of CB -WT, GFAP-CB -RS and GFAPhrGFP-CB -WT mice. Only non-specific gold particles were detected in mouse hippocampi lacking CB receptors. Altogether, we demonstrated the existence of a precise molecular architecture of the CB receptor in astrocytes that will have to be taken into account in evaluating the functional activity of cannabinergic signaling at the tripartite synapse.

Suppression of Presynaptic Glutamate Release by Postsynaptic Metabotropic NMDA Receptor Signalling to Pannexin-1.
The impact of pannexin-1 (Panx1) channels on synaptic transmission is poorly understood. Here, we show that selective block of Panx1 in single postsynaptic hippocampal CA1 neurons from male rat or mouse brain slices causes intermittent, seconds long increases in the frequency of sEPSC following Schaffer collateral stimulation. The increase in sEPSC frequency occurred without an effect on evoked neurotransmission. Consistent with a presynaptic origin of the augmented glutamate release, the increased sEPSC frequency was prevented by bath-applied EGTA-AM or TTX. Manipulation of a previously described metabotropic NMDAR pathway (i.e., by preventing ligand binding to NMDARs with competitive antagonists or blocking downstream Src kinase) also increased sEPSC frequency similar to that seen when Panx1 was blocked. This facilitated glutamate release was absent in transient receptor potential vanilloid 1 (TRPV1) KO mice and prevented by the TRPV1 antagonist, capsazepine, suggesting it required presynaptic TRPV1. We show presynaptic expression of TRPV1 by immunoelectron microscopy and link TRPV1 to Panx1 because Panx1 block increases tissue levels of the endovanilloid, anandamide. Together, these findings demonstrate an unexpected role for metabotropic NMDARs and postsynaptic Panx1 in suppression of facilitated glutamate neurotransmission. The postsynaptic ion and metabolite channel, pannexin-1, is regulated by metabotropic NMDAR signaling through Src kinase. This pathway suppresses facilitated release of presynaptic glutamate during synaptic activity by regulating tissue levels of the transient receptor potential vanilloid 1 agonist anandamide.

THINK TWICE BEFORE YOU KEEP YOURSELF AWAKE!: THE EFFECTS OF TWO DIFFERENT SLEEP DEPRIVATION METHODS ON THE MEMORY CONSOLIDATION OF OBJECT-LOCATION MEMORIES.

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Adithya Sarma, Sophia Wilhelm, Mirthe Ronde, Peter Meerlo, Jean-Christophe Billeter, Robbert Havekes
University of Groningen, Neurobiology Expertise Group, Groningen Institute For Evolutionary Life Sciences (gelifes), Groningen, Netherlands

Sleep deprivation (SD) is a significant health problem in the modern world, with studies showing that average sleep time has decreased by 1.5 hours per night in as little as 50 years. It is widely known that sleep is indispensable for brain function and plays a key role in memory processes. Therefore, the effects of sleep deprivation on the brain have been extensively studied in mammalian models. The most common experimental methods of SD used in rodent models are the gentle handling method (GH) and novelty method. GH involves gently tapping or shaking the cage, whereas the novelty method involves introducing novel objects in the cage. While both methods have been used to examine how sleep loss affects brain plasticity, it is unclear as to how these approaches impact hippocampal memory consolidation. Recent work in our lab has shown that GH for 6 hours impairs hippocampal-dependent memory consolidation by negatively impacting neuronal connectivity. However, it is unclear whether SD using object novelty impacts memory processes as well. In contrast to GH, using novel objects to keep an animal awake presents a very different external stimulus. Consequently, it is plausible that stimulating an animal using two different SD methods could have very different implications on cognition. In the present study, we, therefore, determined how both SD methods affected hippocampal-dependent memory consolidation in the Object Location Memory task. Using this approach, we attempt to discern if the type of SD plays a significant role in affecting memory consolidation.

Time tracking allows an adaptive anticipation of events when supported by memory. The striatum and the hippocampus are known to show strong time-related activity, likely supporting time for action (caudate-putamen) and time for memory, respectively. Here we asked whether their neural activity represents the time of expected events and/or the duration of the intervals separating them. We designed a task based solely on cumulative elapsed time, thereby nesting two duration probabilities (short and intermediate) into a longer one. We recorded neural activity in caudate, putamen and hippocampus of two rhesus macaques categorizing durations into short (.5s), intermediate (1s) or long (2s) above 90% correct. After identifying time-modulated cells in all structures, we asked whether population activity during the longest interval was constant (continuous passage of time) or event-modulated (marking each interval duration or their likely endings). A Support-Vector Machine based decoding showed that time was decoded above chance in all regions. However, there were strong differences between structures. Caudate activity supported decoding with the highest accuracy and temporal resolution throughout the long interval, but weakly modulated by expected events. In contrast, putamen activity supported high decoding accuracy for expected events, while interval transitions followed a stepwise function. At a larger scale, the hippocampus discriminated only the first and the second half of the long interval. Our results suggest that time is represented almost continuously in the caudate, while the putamen and the hippocampus show a discrete representation highlighting times of expected events and their durations, through transitions in population states.

The hippocampus and the medial prefrontal cortex (mPFC) participate in episodic and working memory. Although the neural activity in both areas can be linked to the formation of memory representations, the neural mechanisms involved in learning temporal associations between stimulus and reward are still unknown. In this work, we use head-fixed mice with simultaneous electrophysiological recordings from the hippocampal CA1 subfield and the mPFC with two 128-channel silicon probes to investigate this in an auditory trace conditioning task. Animals had to learn to associate a sensory stimulus (conditioned stimulus; CS) and a reward (unconditioned stimulus; US) separated by a delay (trace period). First, we found that CA1 and mPFC differentially encoded stimulus and reward onset through neuronal temporal sequences. Moreover, CS and US temporal representations disentangled from each other after learning, an effect that was partially reverted in incorrect trials. Additionally, we found that mPFC held a strong and stable representation of stimulus identity after learning, bridging stimulus onset and reward, while in CA1 stimulus identity could be only partially recovered during the trace period. Crucially, a hidden Markov model revealed that the onset of CS-coding states predicted the behavioral performance at a single-trial level in both correct and error trials. Together these results suggest temporal sequences in the hippocampus have a role in the initial processing of the stimulus and encode outcome predictability, while mPFC is important to create the stimulus-reward association and to drive decision making.

Introduction: Typical absence seizures (ASs) of 3-4 Hz thalamocortical spike-wave discharges, are the hallmark of Childhood Absence Epilepsy (CAE). Recent studies in CAE cohorts show 30% of pharmaco-resistance and 60% of patients show psychiatric comorbidities, including attention, cognitive, memory and mood impairments. In humans, there is a pressing need to new therapeutics that address both seizures and comorbidities and to achieve so, a better understanding of ASs animal models behaviour is needed. Aims: Using ASs animal models, the Genetic Absence Epilepsy Rat from Strasbourg (GAERS) and STARGAZER (STG) mice, and respective controls, we aimed to assess behaviour comorbidities in both models. Methods: Behaviour tests were carried out to assess anxiety, locomotion, learning and memory. Synaptic plasticity was assessed by long-term potentiation (LTP) in hippocampal slices. Results: GAERS did not exhibit impaired locomotor activity neither anxiety-like behaviour. Significant differences were found between GAERS and controls in novel object recognition and cross-modal object recognition memory. In the Y-Maze and delayed non-matching to position tasks, deficits were only found for spontaneous alternation working memory. Hippocampal-dependent memory, Barnes Maze test, showed significantly lower performance in GAERS and STG than controls, suggesting impairments in the prefrontal cortex, thalamus, parahippocampal regions, and hippocampal-dependent memory. LTP magnitude in GAERS and STG was significantly lower than that obtained from Wistar and WT animals, respectively. Conclusions: This study suggests memory deficits in GAERS, in spatial working memory and object recognition memory. GAERS and STG models display impaired reference memory, in line with the reduced LTP magnitude.

Background: We have shown that elimination of neuroplastin gene expression from all CNS neurons prevents associative learning resulting in anterograde amnesia. Strikingly, ablation after associative learning results in specific retrograde amnesia. Neuroplastin contributes to synaptic plasticity modulating long-term potentiation (LTP), formation and stabilization of excitatory synapses, and neuronal spinogenesis. Neuroplastin forms a complex with plasma membrane Ca^{2+} ATPase (PMCA) which is essential to pump Ca^{2+} from the cytoplasm to the extracellular space. Neuroplastin-deficient mice display complex cognitive deficits and reduced levels of PMCAs suggesting alterations in Ca^{2+}-dependent signaling. Because selective loss of neuroplastin expression in glutamatergic neurons does not interfere with associative learning, we investigated the necessity of neuroplastin expression in GABAergic interneurons for associative learning and memory. **Methods:** We generated *Nptn*$^{lox/loxGAD2CreERT}$ mice allowing inactivation of the neuroplastin gene in GABAergic interneurons by tamoxifen activation of the GAD2 promoter driven Cre recombinase. Neuroplastin expression was analyzed by immunofluorescence. Associative learning and memory were investigated in a two-way active avoidance paradigm (Shuttle Box) with light as stimulus. **Results:** Neuroplastin immunostaining was selectively reduced in parvalbumin positive interneurons of tamoxifen-treated adult *Nptn*$^{lox/loxGAD2CreERT}$ mice. These mice showed normal acquisition of the two-way active avoidance task. However, ablation of the neuroplastin gene after the successful acquisition of this task resulted in retrograde amnesia with significantly reduced memory. **Conclusions:** Ablation of neuroplastin in GABAergic interneurons is sufficient to induce retrograde amnesia of associations and allows to discriminate mechanisms selective for learning and memory. Our results confirm that neuroplastin is essential for associative learning and memory. *Keywords:* Associative memory, Neuroplastin, GABAergic interneurons, Retrograde amnesia, PMCAs

DISTINCT HIPPOCAMPAL NETWORK STATES SUPPORT THETA PHASE PRECESSION AND THETA SEQUENCES IN CA1

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Matteo Guardamagna, Federico Stella, Francesco Battaglia
Radboud University, Donders Institute, Nijmegen, Netherlands

The hippocampus likely uses temporal coding to represent complex memories via mechanisms such as theta phase precession and theta sequences. Theta sequences are rapid sweeps of spikes from multiple place cells, encoding past or planned trajectories or non-spatial information. Phase precession, the correlation between a place cell's theta firing phase and animal position has been suggested to facilitate sequence emergence. Here we address the relationship of these phenomena by taking advantage of simultaneous recordings of place cells population activity and layer-specific LFP dynamics in the CA1 region. We find that phase precession varies strongly across cells and environmental contingencies. Phase precession is predominantly present when the medium gamma oscillation (60-90 Hz, linked to Entorhinal inputs) dominates the CA1 network state. Conversely, theta sequences are most evident for non-precessing cells or with leading slow gamma (20-45 Hz, linked to CA3 inputs). These results challenge the view that phase precession is the mechanism underlying the emergence of theta sequences and point at a "dual network states" model for the hippocampal temporal code, potentially supporting merging of memory and exogenous information in CA1.

DETERMINING THE RELATIONSHIP BETWEEN MOLECULAR CHANGES IN THE AMYGDALA AND THE EMERGENCE OF ASSOCIATIVE LEARNING IN THE RAT

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Giovanni Pedone[1], Ryan Ward[2], John Reynolds[1]
[1]University of Otago, Anatomy, Dunedin, New Zealand, [2]University of Otago, Psychology, Dunedine North, New Zealand

Understanding the neural basis of learning is a fundamental question facing neuroscientists. Although much is known about the relationship between LTP and consolidated information, we know very little about what happened when the association between an event or behaviour and a consequence is realised. This has been defined as a moment of insight and the specific molecular changes which accompany such moments are not well understood. To shed light on this mechanism we used a classical conditioning protocol paired with an algorithm that allows us to specify when a rat has learned the association between a stimulus (sound) and its outcome (delivery of a food pellet). We quantified the phosphorylation of ERK, a signalling molecule related to learning, in the central amygdala, a region of the brain involved in behaviour driven by the value of a stimulus during normal associative learning and during aberrant behaviour towards addictive stimuli. We found that rats that had experienced the moment of insight expressed significantly more p-ERK than those that did not or those that were overtrained following acquisition. Thus, learning in our paradigm is accompanied by cellular changes that transiently peak when the “moment of insight” occurs and then subside following it.

TWO DISTINCT WAYS TO FORM LONG-TERM OBJECT-RECOGNITION MEMORY DURING SLEEP AND WAKEFULNESS

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Anuck Sawangjit, Maximilian Harkotte, Carlos Oyanedel, Niels Niethard, Jan Born, Marion Inostroza
University of Tübingen, Institute Of Medical Psychology And Behavioral Neurobiology, Tübingen, Germany

Sleep is considered as the brain state that is optimal for long-term memory formation. However, some observations suggest that long-term memory can also be formed in the waking state. Here, we compared the effects of 2-h post-encoding periods of sleep and wakefulness on the formation of long-term memory for objects and their associated environmental contexts. We employed a novel-object recognition (NOR) task in rats, using object exploration and exploratory rearing on hind limbs, respectively, as behavioral indicators of these memories. Rats in both post-encoding wake and sleep conditions showed significant long-term NOR memory at remote recall testing (1-week), with NOR memory after sleep predicted by the occurrence EEG spindle-slow oscillation coupling during sleep. Importantly, rats in the sleep group exhibited a decrease in exploratory rearing at recall testing, revealing successful recall of environmental context. In contrast, the wake rats showed no change in rearing behaviors, suggesting that although NOR memory was present, context memory was lost. Disruption of hippocampal function during the post-encoding interval suppressed long-term NOR memory together with context memory formation, when the rats had slept in this interval, but enhanced NOR memory when they were awake. Also, we show that, under certain conditions (e.g., recognition of objects in a context other than learning), NOR memory in the wake rats was superior to that after sleep. Our findings indicate two distinct and competing modes of long-term memory formation. Sleep consolidation is hippocampus-dependent and implicates event-context binding, whereas wake consolidation is impaired by hippocampal activation and strengthens context-independent representations.

Obesity is associated with adverse cognitive outcomes, particularly those depending on hippocampal function, in humans as well as in animal models. As the endocannabinoid system participates in obesity and regulates memory processes, we address its causal involvement in memory deficits induced by obesogenic high-fat diet (HFD) intake during adolescence in mice. Using a pharmacological approach, we demonstrated that a systemic blockade of the main cannabinoid type 1 receptor (CB1R) rescued HFD-induced deficits of long-term object recognition memory but also normalized training-induced hippocampal c-Fos over-activation as well as aberrant *in vivo* long-term potentiation in CA1 of HFD-fed mice. We then found enhanced CB1R expression and endocannabinoid levels (specifically anandamide) in the hippocampus of HFD-fed mice trained with novel objects in a novel environment and showed that decreasing hippocampal CB1 expression abolished HFD-induced long-term recognition memory deficits. We then investigated which neuronal types (GABA or glutamate) carrying CB1R are responsible for memory impairments in HFD-fed mice. Absence of CB1R from forebrain GABAergic neurons had no effect while specific CB1R deletion on hippocampal glutamatergic cells alleviated HFD-induced long-term recognition memory deficits. Moreover, this CB1R deletion rescued other memory deficits induced by HFD, i.e. social memory and object-in-place memory, and this effect was dependent on CB1R located at the plasma, but not mitochondrial, membrane of hippocampal glutamatergic cells. These results demonstrate that, despite carrying only 5% of hippocampal CB1R, glutamatergic neurons mediate endocannabinoid-induced alterations of hippocampal function in HFD-fed mice.

In addition to metabolic and cardiovascular disorders, obesity is associated with cognitive dysfunction. Similarly, an obesogenic high-fat diet (HFD) consumption in animal models, in particular during adolescence, induces memory deficits. Interestingly, we recent showed that alterations of the hippocampal endocannabinoid system and its main receptor (CB1R), well known to regulate brain plasticity and memory processes, participate in HFD-induced memory deficits in male mice. Indeed, systemic blockade of CB1R or decrease of hippocampal CB1R improved memory in HFD-fed males. This project aims at identifying whether the endocannabinoid system is also central in the memory deficits induced by HFD consumption during adolescence in females and whether similar mechanisms are involved. First, we showed that systemic injection of a CB1R antagonist rescued HFD-induced deficits of long-term recognition memory in females, as previously shown in males, indicating CB1R signaling regulates the impact of HFD on memory function in both sexes. We then evaluated whether hippocampal CB1R are involved in such effects in females. Contrary to males, decrease of CB1R in the dorsal hippocampus (either on glutamatergic neurons or more broadly on all cells) did not improve recognition memory deficits in females. Interestingly, decreasing CB1R in the medial prefrontal cortex rescued recognition memory deficits in females, but not males, suggesting a double dissociation in the CB1R regulation of HFD effect on memory. We are currently comparing the levels of CB1R expression in hippocampus and prefrontal cortex of females and males under HFD and we plan to manipulate sex hormones to better characterize the gender effect.

DECIPHERING THE WAY NEURONAL PATTERNS ARE UTILIZED BY DOWNSTREAM NETWORKS DURING LEARNING

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Amir Levi[1,2], Shirly Someck[1,2], Lidor Spivak[1,2], Hadas Sloin[1,2], Eran Stark[1,2]
[1]Tel Aviv University, Physiology And Pharmacology, Tel Aviv, Israel, [2]Tel Aviv University, Sagol School Of Neuroscience, tel aviv, Israel

Learning has been studied using stimulus-response paradigms, and abundant correlative evidence links learning to changes in network activity. Nevertheless, a causal link between multi-neuronal activity and learning has never been demonstrated. To to determine how network activity underlies learning, we devised a three-step plan: (1) Determining how a neuronal assembly transmits an arbitrary signal to a downstream target; (2) Creating a behavioral task that guarantees ideal conditions for learning; (3) Bypassing the sensory-to-neuronal transformation by directly inducing coding-relevant activity patterns. Here, we report the first two steps. First, we applied optogenetic white-noise signals to groups of neocortical pyramidal cells in freely-moving mice. We found that directly-activated cells exhibited spike timing precision of several milliseconds. Instead of losing precision, postsynaptic interneurons exhibited higher precision with respect to the white-noise signal. Moreover, the postsynaptic spike trains demonstrated error correction. Data-driven modeling showed that nonlinear amplification of coincident presynaptic spikes improved precision. Therefore, error correction via convergence may enable messages to be precisely propagated between neuronal networks. Next, we trained mice on a two-alternative forced-choice task, in which the rules changed every day. After a period of general acquaintance with the apparatus, all mice achieved single-session learning of rules that required discriminating between two visual stimuli. We are now training mice to discriminate between neuronal patterns induced optogenetically. By analyzing learning curves of the induced patterns, we will determine which types of patterns are best utilized by downstream networks for learning.

DEVELOPMENTAL EXPRESSION OF DFOXP IS REQUIRED IN MOTORNEURONS FOR OPERANT SELF-LEARNING IN DROSOPHILA

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Andreas Ehweiner, Björn Brembs
Uni Regensburg, Neurobiologie, Regensburg, Germany

Out of the four FOXP genes in humans the FOXP2 transcription factor was shown to have an unique role in speech learning and articulation. This function is highly conserved as analogous motor learning functions were identified in songbirds, rodents or fruit flies. While *Drosophila* is not a vocal learner, the process of torque learning in tethered flies is an analogous motor learning process to vocal learning. An initially very variable behaviour is being modulated via an operant feedback loop to shape the variable actions to the desired output. Accordingly, the fly orthologue of the FOXP2 gene, *dFoxP* is also involved in this operant self-learning task. Due to the broad expression, it remains unknown which brain regions or gene targets are important for this learning process. We performed different spatial or temporal knockouts of *dFoxP* using CRISPR/Cas9. Knocking out *dFoxP* in individual brain regions did not lead to any learning defects. A knockout of *dFoxP* in all neurons of adult flies showed no immediate effect, but 14 days old flies were impaired in learning. Knocking *dFoxP* out in motorneurons results in an impairment to fly. As protein kinase C (PKC) is required in motorneurons for torque learning, we expressed PKCi, an inhibitor of PKC in *dFoxP isoform B (FoxPiB)*-positive neurons and found a learning impairment. Knocking out only the atypical PKC (aPKC) in motor neurons or *dFoxPiB*-positive neurons via CRISPR/Cas9 also leads to learning defects, suggesting that aPKC is the gene responsible for operant self-learning in *Drosophila*.

THE HIP-MPFC NETWORK IS A NEURAL RESOURCE OF OBJECT RECOGNITION MEMORY

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Julia Buescher[1], Matthias Prigge[2], Magdalena Sauvage[3]
[1]Leibniz Institute of Neurobiology, Neuromodulatory Networks, Magdeburg, Germany, [2]Leibniz Institute for Neurobiology, Neuromodulatory Networks, Magdeburg, Germany, [3]Leibniz Institute, Functional Architecture Of Memory, Magdeburg, Germany

How well we remember objects and their location varies from person to person. But what are the neuronal substrates of these interindividual differences? To form an object memory, different features of an object are encoded in different brain areas as interconnected and activity related neurons (engrams). Remembering objects relies on connections between engram ensembles located in different brain areas. It has been suggested that hippocampus (HIP) engram ensembles encode recent memory recall while medial prefrontal cortex (mPFC) engram ensembles participate in remote memory after consolidation. The HIP and mPFC display a strong functional and anatomical interconnection which plays a crucial role in object location memory processes. We argue that variability in HIP-mPFC connectivity and early recruiting of mPFC engrams ensembles are giving rise to interindividual performance differences in an object location task. We employ an object-in-place task to test our hypothesis. First, we identify neurons that contribute to the engram coding for an object location through a video-assisted close-loop photolabeling of active neurons with CAMPARI2. We quantify the amount of active neurons in the mPFC among individual mice and correlate it with individual behavioural performance to analyse if neuronal ensemble-size correlates with object recognition performance. Currently, a first cohort of animals injected with CAMPARI2 is trained in the object-in-place task. We postulate that the mice which are performing better in the behavioural task recruit more mPFC neurons during object recognition compared to mice showing low performance in the task.

EVIDENCE OF SEX-DEPENDENT INVOLVEMENT OF THE MEDIAL PREFRONTAL CORTEX IN SOCIAL MEMORY IN JUVENILE RATS

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Aseel Yaseen, Maroun
Haifa University, Neurobiology, Haifa, Israel

The medial-prefrontal-cortex (mPFC) is critical for social behavior. One characteristic of the mPFC is its protracted maturation through juvenility. Using blockade of de novo protein synthesis in the mPFC, we previously showed that the mPFC plays a critical role in mediating the consolidation of long-term social-recognition-memory (SRM) in juvenile male rat (Yaseen et al., 2018). This present study investigates whether the role of the mPFC in mediating SRM is sexually dimorphic. For this purpose, we microinjected anisomycin into the mPFC of male and female juvenile and adult rats and examined its effect on the ability to recognize a new conspecific. Our results showed deficits in SRM only in juvenile-males without affecting adult-males or juvenile-females. In order to examine mPFC activation during SRM, we used immunoshitochemoisty to assess cFos expression, the neuronal activation marker. We collected brains 90-min after the long-term SRM-test and quantified the number of cFos cells. We observed increases in the expression of cFos in juvenile-males but not juvenile-females or adult males and females. These results may suggest that in males, with maturation there is a transition from mPFC-dependent SRM in juveniles to mPFC-independent SRM in adults. However, among females we did not observe any differences between the age groups and both showed independency of SRM on mPFC. These findings point to a need for sex-specific treatments of social disorders in children.

Sex-dimorphic role of prefrontal oxytocin receptors in social-induced facilitation of extinction in juvenile rats.
We previously reported that in the adult animal extinction in pairs resulted in enhanced extinction, showing that social presence can reduce previously acquired fear responses. Based on our findings that juvenile and adult animals differ in the mechanisms of extinction, here we address whether the social presence of a conspecific affects extinction in juvenile animals similarly to adults. We further address whether such presence has a different impact on juvenile males and females. To that end, we examined in our established experimental setting whether conditioned male and female animals extinguish contextual fear memory better while in pairs. Taking advantage of the role of oxytocin (OT) in the mediation of extinction memory and social interaction, we also study the effect of antagonizing the OT receptors (OTR) either systemically or in the prefrontal cortex on social interaction-induced effects of fear extinction. The results show that social presence accelerates extinction in males and females as compared to the single condition. Yet, we show differential and opposing effects of an OTR antagonist in both sexes. Whereas in females, the systemic application of an OTR antagonist is associated with impaired extinction, it is associated with enhanced extinction in males. In contrast, prefrontal OT is not engaged in extinction in juvenile males, while is it is critical in females. Previously reported differences in the levels of prefrontal OT between males and females might explain the differences in OT action. These results suggest that even during the juvenile period, critical mechanisms are differently involved in the regulation of fear in males and females.

Acute social isolation and regrouping cause short- and long-term molecular changes in the rat medial amygdala.
Social isolation poses a severe mental and physiological burden on humans. Most animal models that investigate this effect are based on prolonged isolation, which does not mimic the milder conditions experienced by people in the real world. We show that in adult male rats, acute social isolation causes social memory loss. This memory loss is accompanied by significant changes in the expression of specific mRNAs and proteins in the medial amygdala, a brain structure that is crucial for social memory. These changes particularly involve the neurotrophic signaling and axon guidance pathways that are associated with neuronal network remodeling. Upon regrouping, memory returns, and most molecular changes are reversed within hours. However, the expression of some genes, especially those associated with neurodegenerative diseases remain modified for at least a day longer. These results suggest that acute social isolation and rapid resocialization, as experienced

by millions during the COVID-19 pandemic, are sufficient to induce significant changes to neuronal networks, some of which may be pathological.

Prefrontal Oxytocin is Involved in Impairments in Prefrontal Plasticity and Social Memory Following Acute Exposure to High Fat Diet in Juvenile Animals.
Juvenility represents a critical developmental phase during which exposure to a high fat diet (HFD) can severely modify cognitive and emotional functioning. The purpose of this study was to address how short and acute exposure to a HFD during juvenility affects social memory recognition and prefrontal long-term potentiation (LTP). As LTP and social memory depend on the neuromodulator oxytocin (OXY) and due to its role in metabolism, we also examined the effects of OXY in mediating HFD-induced alterations in social memory and LTP. Our results show that short exposure to a HFD during juvenility impairs social preference memory and prefrontal LTP. Interestingly, whereas systemic injections of OXY reversed the impairments in HFD-fed animals and impaired LTP and memory in control animals; prefrontal injections of the OXY agonist TGOT reversed the effects in HFD animals without affecting control animals. Exposure to HFD was associated with a reduction in the levels of OXY in the prefrontal compared to control animals. Interestingly, the restoration of social memory by TGOT in HFD animals was also associated with normalization of OXY in the prefrontal. These results point to a role that prefrontal OXY has in mediating the effects of HFD on memory and plasticity.

HIPPOCAMPAL-THALAMIC-CORTICAL PATHWAYS MODULATE REMOTE MEMORY RETRIEVAL.

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Charlotte Andrews, Nekane Balcells Picaza, Gisella Vetere
ESPCI, Plasticité Du Cerveau, Paris, France

Brain-wide mapping of immediate early gene revealed a strong hippocampal-thalamic-cortical signature in the brain network active during remote fear memory recall. We aim to unravel the contribution of hippocampal-thalamic-cortical circuitry in processing long-lasting memories with a spatial and emotional component. Graph theory analysis of memory networks showed that the anterodorsal thalamic nucleus (ADn) activity positively correlates with other regions during recent memory recall but during remote recall, this pattern switches and, ADn activity negatively correlated with the majority of the other network regions analyzed. This suggests that the inhibition of the ADn by other regions is required during the recall of a remote memory. Using optogenetics *in vivo*, we targeted the anterior cingulate cortex (aCC)-ADn pathway and the hippocampal CA3-ADn pathway, as both aCC and hippocampus are important in long-term memory formation and recall. Results show that optogenetic inhibition of CA3, but not aCC, excitatory projections to the ADn, leads to impaired memory performances with a related change in cellular activity in the CA3, ADn, and aCC, during optogenetic modulation. We also studied the contribution of CA3-ADn and aCC-ADn pathways in the generalization of remote memories by placing the animals in a different context and we used fiber photometry combined with optogenetics to confirm neuronal activity modulation.

THE DEFICITS OF RECOGNITION AND MEMORY IN ADOLESCENCE BY NEONATAL MATERNAL SEPARATION

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Sukwon Lee, Sangyep Shin
Korea Brain Research Institute, Developmental Disorders And Rare Disease Research Group, Daegu, Korea, Republic of

Neonatal maternal separation (MS) has been shown to be associated with an increased vulnerability to psychiatric illnesses such as anxiety and depression in animal models. As society progresses, separation situations and isolation from parents have occurred in human lives. The present study aims to investigate the behavioral alternation induced by neonatal maternal separation in the adolescent period during which the brain refine and integrate structures and functions. Following a periodic neonatal MS (4-hour a day, postnatal 2~20, consecutive 19 days), adolescent mice were employed for a series of behavioral assessments for locomotion, anxiety, recognition, learning, memory, and fear learning using open field test, novel object recognition memory test, object location memory test, social interaction test, and auditory fear conditioning. The results showed that MS mice showed decreased cognition memory to the new objects and places based on the novel object recognition memory and object location memory test. In addition, MS mice scored lower alternation index in the Y-maze test. Furthermore, MS mice had a short latency time to fall, this result also reflects impaired motor learning ability. Therefore, these results indicate that early life stress based on MS may induce deficits of recognition and learning ability during adolescence.

STRESS-INDUCED SOCIAL ODOR PREFERENCE IS DISRUPTED BY ADOLESCENT HIGH-FAT DIET CONSUMPTION: IS HIPPOCAMPAL CA2 AREA INVOLVED?

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Alice Fermigier[1], Eva-Gunnel Ducourneau[1], Ioannis Bakoyiannis[1], Mateo N'Diaye[1], Vivien Chevaleyre[2], Rebecca Piskorowski[2], Guillaume Ferreira[1]

Juvenile obesity is a concerning public health issue associated with many adverse outcomes, including cognitive impairments. This can be replicated using animal models, as rodents fed a high fat diet (HFD) throughout adolescence display social memory dysfunction at adulthood. We recently showed that adolescent HFD-induced social memory deficits are mediated by hippocampal overactivity as they can be reversed by chemogenetic silencing of hippocampal pyramidal neurons. As olfaction is essential for rodent social behavior, we here investigate the impact of HFD on social odor recognition and the involved brain circuits, focusing on the hippocampus. Our first results indicate that control diet-fed mice prefer investigating their own bedding over a novel bedding, but only after foot-shocks, suggesting stress influences social odor preference. Interestingly, adolescent HFD-fed animals do not show such preference (before or after foot-shocks) and a large chemogenetic inactivation of hippocampal pyramidal neurons rescues these deficits. We then focused on the CA2 area of the hippocampus, known for its important role in social memory, and observed that specific chemogenetic silencing of CA2 pyramidal neurons alleviates HFD-induced deficits in social odor preference. Altogether, this suggests the effect of HFD on social odor preference is mediated by an overactivity of CA2 pyramidal neurons. Future experiments will characterize the effects of stress on social odor preference and will further evaluate HFD-induced CA2 overactivity using *ex vivo* electrophysiology and *in vivo* photometry-based calcium imaging. This will provide insight on how the CA2 area might be involved in the interaction between stress, social function and diet.

DISTINCT ROLES OF PREFRONTAL CORTEX SUBREGIONS IN THE CONSOLIDATION AND RECALL OF REMOTE SPATIAL MEMORIES

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Mattia Santoboni[1], Eleonora Centofante[1,2], Elena Mombelli[1], Sara Pezza[1], Arianna Rinaldi[1], Andrea Mele[1]
[1]Sapienza Universtiy of Rome, Biology And Biotechnology - "charles Darwin", Centre For Research In Neurobiology - D. Bovet, Roma, Italy, [2]Institute of Biophysics, National Research Council, Palermo, Italy

It is a common believe that memories with time become progressively independent of the hippocampus and are gradually stored in cortical areas. This view is mainly based on evidence demonstrating a role of the medial prefrontal cortex (mPFC) in the retrieval of remote memories. What is more controversial is whether activity in the mPFC is required immediately after learning to initiate the process. Further question are possible functional differences among the different component of the mPFC in the formation and storage of remote memories. To address these issues, we directly contrasted the effects of loss-of-function manipulations of the the anterior cingulate cortex (aCC) and the vmPFC, that includes the infralimbic (IL) and the prelimbic (PL) cortices, immediately after training, and before testing, on the ability of CD1 mice to recall the location of the hidden platform in the Morris water maze (MWM). To this aim we injected in the vmPFC or in the aCC an AAV carrying the hM4Di receptor. Post-training systemic administrations of CNO (3mg/Kg) impaired memory recall at remote (30 days) but not recent (24 hours) time points in both experimental groups. Interestingly, pre-test administrations of CNO revealed that the aCC but not the vmPFC is necessary to the recall of remote spatial information. Overall, these findings revealed a functional dissociation between the two prefrontal areas, demonstrating that they are both involved in the early consolidation of remote spatial memories, but that only the aCC is engaged in their recall.

LACTATE SUPPLY OVERTAKES GLUCOSE WHEN NEURAL COMPUTATIONAL AND COGNITIVE LOADS SCALE UP

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Yulia Dembitskaya[1], Charlotte Piette[1], Sylvie Perez[1], Hugues Berry[2], Pierre Magistretti[3], Laurent Venance[1]
[1]Collège de France, Center For Interdisciplinary Research In Biology (cirb), Paris, France, [2]University of Lyon, INRIA, Liris Umr5205, Villeurbanne, France, [3]KAUST, Biological And Environmental Sciences And Engineering, Thuwal, Saudi Arabia

The neural computational power is determined by neuroenergetics, but how and which energy substrates are allocated to various forms of memory engram is unclear. To solve this question, we asked whether neuronal fueling by glucose or lactate scales differently upon increasing neural computation and cognitive loads. Here, using in vitro and in vivo electrophysiology, two-photon imaging, cognitive tasks and mathematical modeling, we show that in hippocampus both glucose and lactate are involved in engram formation, with lactate supporting long-term synaptic plasticity evoked by high stimulation load activity patterns and high attentional load in cognitive tasks , and glucose being sufficient for less demanding neural computation and learning tasks. Indeed, i) we show that lactate is mandatory for demanding neural computation, while glucose is sufficient for lighter forms of activity-dependent long-term potentiation (LTP), ii) we find that subtle variations of spike amount or frequency in spike-timing-dependent plasticity (STDP) are sufficient to shift the energetic dependency from glucose to lactate, and iii) we demonstrate that lactate is necessary for a cognitive task requiring high attentional load such as the object-in-place task and for the corresponding *in vivo* hippocampal LTP expression, but is not needed for a less demanding task such as a simple novel object recognition. Overall, these results demonstrate that glucose and lactate metabolisms are differentially engaged in neuronal fueling depending on the complexity of the activity-dependent plasticity and behavior.

HIPPOCAMPO-CORTICAL ENGRAM CIRCUITS REGULATE REMOTE CONTEXTUAL MEMORY AND GENERALIZATION

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Gabriel Berdugo-Vega
École Polytechnique Fédérale Lausanne (EPFL), Laboratory Of Neuroepigenetics, Brain Mind Institute, School Of Life Sciences, Lausanne, Switzerland

The indexing theory of consolidation postulates that cortical memory representations are indexed and reinstated by the hippocampus to ensure recall at remote times, but formal validation for this theory is missing. Furthermore, engrams cells were suggested to provide a cellular substrate for memory indexes, but a direct role of hippocampal engrams in indexing cortical activity at remote times is lacking. Here, we attempt to investigate both hypotheses by identifying ventral hippocampal (vCA1) engrams monosynaptically projecting to the medial prefrontal cortex (mPFC), a known depository of remote memories, and by assessing their potential role in indexing cortical engram activity at remote times. For this, we used a combination of retrograde viral tracing coupled to engram identification and chemo/opto-genetic manipulations following contextual fear conditioning and remote recall. Our data suggests the presence of two projection components within the vCA1 to mPFC circuit, either at the service of memory precision (engram specific) or generalization (non-engram specific). Further, hippocampal input determines engram reactivation in the mPFC and influences generalization and memory recall. Altogether, our results highlight the influence of hippocampal input on cortical activity for remote recall and further deepens our understanding on the contribution of engram circuits to remote memory consolidation.

De novo DNA methylation controls neuronal maturation during adult hippocampal neurogenesis.
Adult neurogenesis enables the life-long addition of functional neurons to the hippocampus and is regulated by both cell-intrinsic molecular programs and behavioral activity. De novo DNA methylation is crucial for embryonic brain development, but its role during adult hippocampal neurogenesis has remained unknown. Here, we show that de novo DNA methylation is critical for maturation and functional integration of adult-born neurons in the mouse hippocampus. Bisulfite sequencing revealed that de novo DNA methyltransferases target neuronal enhancers and gene bodies during adult hippocampal neural stem cell differentiation, to establish neuronal methylomes and facilitate transcriptional up-regulation of neuronal genes. Inducible deletion of both de novo DNA methyltransferases Dnmt3a and Dnmt3b in adult neural stem cells did not affect proliferation or fate specification, but specifically impaired dendritic outgrowth and synaptogenesis of newborn neurons, thereby hampering their functional maturation. Consequently, abolishing de novo DNA methylation modulated activation patterns in the hippocampal circuitry and caused specific deficits in hippocampus-dependent learning and memory. Our results demonstrate that proper establishment of neuronal methylomes during adult neurogenesis is fundamental for hippocampal function.

Adult-born neurons promote cognitive flexibility by improving memory precision and indexing.
Adult neurogenesis in the hippocampal dentate gyrus (DG) is an extraordinary form of plasticity fundamental for cognitive flexibility. Recent evidence showed that newborn neurons differentially modulate input to the infra- and supra-pyramidal blades of the DG during the processing of spatial and contextual information, respectively. However, how this differential regulation by neurogenesis is translated into different aspects contributing cognitive flexibility is unclear. Here, we increased adult-born neurons by a genetic expansion of neural stem cells and studied their influence during navigational learning. We found that increased neurogenesis improved both memory precision and flexibility. Interestingly, each of these gains was associated with distinct subregional patterns of activity and better separation of memory representations in the DG-CA3 network. Our results highlight the role of adult-born neurons in promoting memory precision and indexing and suggests their anatomical allocation within specific DG-CA3 compartments, together contributing to cognitive flexibility.

Increasing neurogenesis refines hippocampal activity rejuvenating navigational learning strategies and contextual memory throughout life.
Functional plasticity of the brain decreases during ageing causing marked deficits in contextual learning, allocentric navigation and episodic memory. Adult neurogenesis is a prime example of hippocampal plasticity promoting the contextualisation of information and dramatically decreases during ageing. We found that a genetically-driven expansion of neural stem cells by overexpression of the cell cycle regulators Cdk4/cyclinD1 compensated the age-related decline in neurogenesis. This triggered an overall inhibitory effect on the trisynaptic hippocampal circuit resulting in a changed profile of CA1 sharp-wave ripples known to underlie memory consolidation. Most importantly, increased neurogenesis rescued the age-related switch from hippocampal to striatal learning strategies by rescuing allocentric navigation and contextual memory. Our study demonstrates that critical aspects of hippocampal function can be reversed in old age, or compensated throughout life, by exploiting the brain's endogenous reserve of neural stem cells.

GFAP immunoreactivity within the rat nucleus ambiguus after laryngeal nerve injury.
Changes that occur in astroglial populations of the nucleus ambiguus after recurrent (RLN) or superior (SLN) laryngeal nerve injury have hitherto not been fully characterised. In the present study, rat RLN and SLN were lesioned. After 3, 7, 14, 28 or 56 days of survival, the nucleus ambiguus was investigated by means of glial fibrillary acidic protein (GFAP) immunofluorescence or a combination of GFAP immunofluorescence and the application of retrograde tracers. GFAP immunoreactivity was significantly increased 3 days after RLN resection and it remained significantly elevated until after 28 days post injury (dpi). By 56 dpi it had returned to basal levels. In contrast, following RLN transection with repair, GFAP immunoreactivity was significantly elevated at 7 dpi and remained significantly elevated until 14 dpi. It had returned to basal levels by 28 dpi. Topographical analysis of the distribution of GFAP immunoreactivity revealed that after RLN injury, GFAP immunoreactivity was increased beyond the area of the nucleus ambiguus within which RLN motor neuron somata were located. GFAP immunoreactivity was also observed in the vicinity of neuronal somata that project into the uninjured SLN. Similarly, lesion of the SLN resulted in increased GFAP immunoreactivity around the neuronal somata projecting into it and also in the vicinity of the motor neuron somata projecting into the RLN. The increase in GFAP immunoreactivity outside of the region containing the motor neurons projecting into the injured nerve, may reflect the onset of a regenerative process attempting to compensate for impairment of one of the laryngeal nerves and may occur because of the dual innervation of the posterior cricoarytenoid muscle. This dual innervation of a very specialised muscle could provide a useful model system for studying the molecular mechanisms underlying axonal regeneration process and the results of the current study could provide the basis for studies into functional regeneration following laryngeal nerve injury, with subsequent application to humans.

Somatotopic changes in the nucleus ambiguus after section and regeneration of the recurrent laryngeal nerve of the rat.
Changes in motoneurons innervating laryngeal muscles after section and regeneration of the recurrent laryngeal nerve (RLN) are far from being understood. Here, we report the somatotopic changes within the nucleus ambiguus (Amb) after the nerve injury and relates it to the resulting laryngeal fold impairment. The left RLN of each animal was transected and the stumps were glued together using surgical fibrin glue. After several survival periods (1, 2, 4, 8, 12, 16 weeks; at least six rats at each time point) the posterior cricoarytenoid (PCA) and thyroarytenoid (TA) muscles were injected with fluorescent-conjugated cholera toxin and the motility of the vocal folds evaluated. After section and subsequent repair of the RLN, no movement of the vocal folds could be detected at any of the survival times studied and the somatotopy and the number of labeled motoneurons changed. From 4 wpi award, the somatotopy was significantly disorganized, with the PCA motoneurons being located rostrally relative to their normal location. A rostrocaudal overlap between the two pools of motoneurons supplying the PCA and TA muscles was observed from 2 wpi onwards. Hardly any labeled neurons were found in the contralateral Amb in any of the experimental groups. An injury of the RLN leads to a reinnervation of the denervated motor endplates of PCA and TA. However, misdirected axons sprout and regrowth from the proximal stump to the larynx. As a result, misplaced innervation of muscles results in a lack of functional recovery of the laryngeal folds movement following a RLN injury.

LEARNING-DEPENDENT RECONFIGURATION OF HIPPOCAMPAL-PREFRONTAL SYNAPTIC COMMUNICATION

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Chun-Lei Zhang, Christoph Schmidt-Hieber
Institut Pasteur, Université de Paris, Neuroscience Department, Paris, France

Communication between the hippocampus and the neocortex is thought to be critical for long-term memory storage. High-frequency ripple oscillations, observed most prominently in the hippocampal CA1 area, are associated with this communication. However, how this process is implemented at the level of synapses and circuits in the neocortex remains largely unexplored. Here we address this question by performing *in vivo* whole-cell patch-clamp recordings in the secondary motor cortex (MOs) while simultaneously recording the local field potential in CA1 of head-fixed mice exposed to a virtual-reality environment. Following training in a goal-directed spatial task, we observe a learning-dependent membrane potential depolarization in most MOs neurons during hippocampal ripples. In untrained mice, such a depolarization can be mimicked by chemogenetic inactivation of parvalbumin-positive (PV+) interneurons during ripples. Similarly, optogenetic stimulation of hippocampal inputs during inactivation of PV+ interneurons in MOs allows us to reproduce the depolarization. By contrast, in trained animals, the ripple-associated depolarization can be abolished by inactivation of somatostatin-positive (SOM+) interneurons. Together, we provide evidence that local inhibitory neurons play distinct roles in shaping synaptic dynamics when prefrontal cortex neurons integrate hippocampal inputs during ripples after learning. Our results help to understand the synaptic basis of hippocampal-prefrontal communication during memory consolidation.

NEIL3-MEDIATED EPIGENETIC REGULATION OF HIPPOCAMPAL FUNCTION IN MEMORY

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Marion Fernandez-Berrocal[1], Anna Bugaj[1], Nicolas Kunath[1], Robert Marthinsen[1], Vidar Saasen[1], Mina Heggedal[1], Dagny Døskeland[1], Konstanse Innvær[1], Magnar Bjørås[1,2], Jing Ye[1]

Aim: DNA Base Excision Repair (BER) plays an important role in the active DNA demethylation, contributing to the dynamic turnover of DNA modifications. However, it is not clear whether BER-mediated DNA demethylation is required for cortical brain functions. NEIL3 DNA glycosylase is known to initiate BER, recognize DNA demethylation intermediates, and modulate gene expression in hippocampal neurons. In this study, we aim to elucidate the impact of NEIL3 on the neuronal epigenome associated with hippocampal function in memory.
Methods: We evaluated the impact of NEIL3 loss on short-term and long-term spatial memory components using behavioral tasks such as Y-maze and Novel Object Location (NOL). We assessed spatial experience induced expressing of Immediate Early Genes (IEGs) using immunohistochemistry (IHC) and confocal microscopy. We investigated the functional plasticity of hippocampal place cells using electrophysiology strategies. Last, we explore how NEIL3 impacts the epigenome of hippocampal neurons using state-of-the-art sequencing of DNA methylation and hydroxy-methylation.
Results: NEIL3-deficient mice show impaired long-term spatial memory in both Y-maze and NOL tasks. Consistently, NEIL3-depleted hippocampal neurons are functionally impaired by showing (i) reduced IEG-induced memory traces, (ii) differentially regulated memory-related genes, and (iii) deteriorated long-term spatial stability of hippocampal place cells. We are exploring NEIL3-dependent DNA methylation changes in hippocampal neurons using TET-assisted and chemical-assisted pyridine borane sequencing (TAPS and CAPS) technologies.
Conclusion: Our studies suggest an important role NEIL3 in modulating the functionality of hippocampal neurons in spatial memory by shaping the neuronal epigenome and gene expression.

DNA repair enzyme NEIL3 enables a stable neural representation of space by shaping transcription in hippocampal neurons.
DNA repair enzymes are essential for the maintenance of the neuronal genome and thereby proper brain functions. Emerging evidence links DNA repair to epigenetic gene regulation; however, its contribution to different transcriptional programs required for neuronal functions remains elusive. In this study, we identified a role of the DNA repair enzyme NEIL3 in modulating the maturation and function of hippocampal CA1 neurons by shaping the CA1 transcriptome during postnatal development and in association with spatial behavior. We observed a delayed maturation in CA1 and identified differentially regulated genes required for hippocampal development. We revealed impaired spatial stability in CA1 place cells and found spatial experience-induced gene expression essential for synaptic plasticity. This is the first study that links molecular underpinnings of DNA repair to the neural basis of spatial cognition beyond animals' behavioral phenotypes, thus shedding light on the molecular determinants enabling a stable neural representation of space.

NEIL1 and NEIL2 DNA glycosylases modulate anxiety and learning in a cooperative manner in mice.
Oxidative DNA damage in the brain has been implicated in neurodegeneration and cognitive decline. DNA glycosylases initiate base excision repair (BER), the main pathway for oxidative DNA base lesion repair. NEIL1 and NEIL3 DNA glycosylases affect cognition in mice, while the role of NEIL2 remains unclear. Here, we investigate the impact of NEIL2 and its potential overlap with NEIL1 on behavior in knockout mouse models. Neil1Neil2 mice display hyperactivity, reduced anxiety and improved learning. Hippocampal oxidative DNA base lesion levels are comparable between genotypes and no mutator phenotype is found. Thus, impaired canonical repair is not likely to explain the altered behavior. Electrophysiology

suggests reduced axonal activation in the hippocampal CA1 region in Neil1Neil2 mice and lack of NEIL1 and NEIL2 causes dysregulation of genes in CA1 relevant for synaptic function. We postulate a cooperative function of NEIL1 and NEIL2 in genome regulation, beyond canonical BER, modulating behavior in mice.

Genetic interaction between the non-homologous end-joining factors during B and T lymphocyte development: In vivo mouse models.
Non-homologous end joining (NHEJ) is the main DNA repair mechanism for the repair of double-strand breaks (DSBs) throughout the course of the cell cycle. DSBs are generated in developing B and T lymphocytes during V(D)J recombination to increase the repertoire of B and T cell receptors. DSBs are also generated during the class switch recombination (CSR) process in mature B lymphocytes, providing distinct effector functions of antibody heavy chain constant regions. Thus, NHEJ is important for both V(D)J recombination and CSR. NHEJ comprises core Ku70 and Ku80 subunits that form the Ku heterodimer, which binds DSBs and promotes the recruitment of accessory factors (e.g., DNA-PKcs, Artemis, PAXX, MRI) and downstream core factors (XLF, Lig4 and XRCC4). In recent decades, new NHEJ proteins have been reported, increasing complexity of this molecular pathway. Numerous in vivo mouse models have been generated and characterized to identify the interplay of NHEJ factors and their role in development of adaptive immune system. This review summarizes the currently available mouse models lacking one or several NHEJ factors, with a particular focus on early B cell development. We also underline genetic interactions and redundancy in the NHEJ pathway in mice.

Leaky severe combined immunodeficiency in mice lacking non-homologous end joining factors XLF and MRI.
Non-homologous end-joining (NHEJ) is a DNA repair pathway required to detect, process, and ligate DNA double-stranded breaks (DSBs) throughout the cell cycle. The NHEJ pathway is necessary for V(D)J recombination in developing B and T lymphocytes. During NHEJ, Ku70 and Ku80 form a heterodimer that recognizes DSBs and promotes recruitment and function of downstream factors PAXX, MRI, DNA-PKcs, Artemis, XLF, XRCC4, and LIG4. Mutations in several known NHEJ genes result in severe combined immunodeficiency (SCID). Inactivation of or in mice results in normal or mild phenotype, while combined inactivation of or / leads to late embryonic lethality. Here, we describe three new mouse models. We demonstrate that deletion of rescues embryonic lethality in mice with combined deficiencies of and . Furthermore, and mice possess reduced body weight, severely reduced mature lymphocyte counts, and accumulation of progenitor B cells. We also report that combined inactivation of results in live-born mice with modest phenotype, and combined inactivation of results in embryonic lethality. Therefore, we conclude that XLF is functionally redundant with MRI and PAXX during lymphocyte development Moreover, genetically interacts with and

RECENT AND REMOTE SPATIAL MEMORY FORMATION IN INFANT AND ADULT RATS

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Xia Shan[1,2], María Contreras[1,2], Jan Born[1,3], Marion Inostroza[1]
[1]Institute of Medical Psychology and Behavioral Neurobiology, University Of Tübingen, Tuebingen, Germany, [2]Graduate school of Neural & Behavioural Science, International Max Planck Research School, Tuebingen, Germany, [3]Center for integrative neuroscience, University Of Tübingen, Tuebingen, Germany

The infantile brain undergoes developmental changes on structural, connectivity, and molecular levels, and brain functioning may change in quality. Episodic (spatial) memories are processed within hippocampal and neocortical circuits, which have a protracted development. Against this backdrop, we asked whether and how the formation of long-term allocentric spatial memory representations differs between infantile and adult rats, testing recent and remote kinds of these memories. Infant rats on postnatal day (PD)18 and adults rats (PD80) were tested on the object place recognition (OPR) task (which was adapted to the infant rats' early age) using, for the test of recent memory, a 90-min retention interval between sampling phase and testing phase, and for the test of remote memory, a 2-month retention interval between sampling and testing. Adult rats showed OPR memory for the 90-min retention interval (i.e., recent memory), but not at the remote test after two months. In contrast, the pre-weanling rats (on PD18) did not display recent OPR memory, but surprisingly, showed significant remote OPR memory when tested 2 months later and these animals were already in an early adulthood age. The data point to differences in forming and expressing recent and remote spatial memories between pre-weanling and adult rats. In ongoing studies, we are examining the brain areas possibly mediating the differential memory performance in the two age groups.

EXPLORING OFFLINE MEMORY CONSOLIDATION IN GOAL-DIRECTED SENSORIMOTOR TASKS

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Lila Banterle, Alejandro Osorio-Forero, Romain Cardis, Georgios Foustoukos, Najma Cherrad, Laura Fernandez, Anita Lüthi

The sleeping brain is thought to support offline memory consolidation. Critical for this are sleep's electrical brain rhythms that enable transfer of memory traces between distant brain areas and promote synaptic plasticity at specific sets of cortical synapses for long-term storage. An outstanding challenge in the field is to define these roles in the setting of a defined cortical circuit engaged in learning. Amongst the many learning tasks executed by rodents, goal-oriented sensorimotor tasks have been well characterized in terms of the site and timing of cortical circuit plasticity. Therefore, we chose a two-tone auditory discrimination task that required head-fixed and water-restricted mice to discriminate between a go- (8 kHz) and a no-go (12 kHz) tone to obtain a water reward. Mice learned over 7-14 days to become experts (d'=1.5-2). Across days, mice improved performance by reducing the False Alarm rate, which corresponds the no-go tone response, and by suppressing unspecific licking ahead of the tones. Along each daily training session, we observed that the performance evolved across time according to three discrete windows. In a first window, mice seemed to recall what they remembered from the previous day, akin to a proxy for offline consolidation of memory traces acquired in the preceding day. Subsequently, mice exhibited within-session learning. Finally, mice disengaged with the decrease in motivation toward the end of the session. Currently, we are examining the role of discrete brain areas in the dynamics of this learning process through using closed-loop optogenetic inhibition specifically during non-rapid-eye-movement sleep.

MULTISENSORY LEARNING EXPANDS A MEMORY ENGRAM

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Pedro Jacob, Zeynep Okray, Ciara Stern, Kieran Desmond, Nils Otto, Scott Waddell
Centre for Neural Circuits and Behaviour, University of Oxford, Dpag, Oxford, United Kingdom

Life is a multisensory experience for most animals. Learning to associate and bind different sensory features into a scene is a fundamental process of the brain, which improves subsequent memory performance. However, neural mechanisms that bind sensory features during learning remain to be explained. We developed new multisensory aversive and appetitive memory paradigms in *Drosophila* which combine visual and olfactory cues. Flies trained with combinations of both modalities show improved memory performance, even when the sensory cues are presented separately during testing. We used temporal control of neuronal function to define the components of the mushroom body memory network that are required for multisensory learning and performance enhancement. Calcium imaging in head-fixed flies revealed that dopaminergic reinforcement during multisensory learning binds activity in streams of modality-specific Kenyon Cells. After learning a unimodal sensory input generates a multimodal neuronal response. This cross-modal binding and expansion of the memory engram underlies improved memory performance.

NEURONAL UNDERPINNINGS OF EPISODIC-LIKE MEMORY IN THE MOUSE LATERAL ENTORHINAL CORTEX

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Francesca Tozzi[1], Camilla Paraciani[2], Lorenza Tamberi[3], Marco Mainardi[3], Antonino Cattaneo[1,4], Nicola Origlia[3]
[1]Scuola Normale Superiore, Bio@sns, Pisa, Italy, [2]University of Groningen, Groningen Institute For Evolutionary Life Sciences, Groningen, Netherlands, [3]CNR, Institute Of Neuroscience, Pisa, Italy, [4]EBRI, European Brain Research Institute Rita Levi-montalcini, Roma, Italy

Increasing evidence indicates that the Entorhinal Cortex (EC) might play a fundamental role in the formation and recall of episodic memories. We aim to dissect the neuronal underpinnings of episodic memory and establish a causal link between the activity of lateral EC (LEC) neuronal ensembles and the recall of past events that occurred in a specific spatiotemporal context. Using in vivo inhibitory/excitatory chemogenetics and the novel object-place-context recognition test (OPCRT), we showed that the activity of the neuronal ensembles previously engaged in the learning process is necessary and sufficient for memory recall. Moreover, multi-area cfos analysis confirmed the specific EC engagement 2h following either pure spatial navigation or memory processing. Although the EC subdivisions show a similar pattern of cfos staining, in vitro electrophysiology in brain slices revealed a specific long-lasting change in synaptic plasticity only in the LEC. Synaptic plasticity in the LEC intrinsic circuitry was affected only in slices obtained from mice subjected to OPCRT but not in those from mice that were exposed only to the context. Taken together, our results suggest that the LEC can form internal representations of past experiences, retain a trace of their occurrence and participate in their recall.

THE EMOTIONAL AND COGNITIVE DIFFERENCES BETWEEN NOVICES AND BEGINNERS ADULT PROGRAMMERS DURING AN INTRODUCTORY TASK ON CODE.ORG : PRELIMINARY RESULTS

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Hugo Lapierre[1], Patrick Charland[1], Pierre-Majorique Léger[2]
[1]Université du Québec à Montréal, Didactique, Montreal, Canada, [2]HEC-Montréal, Information Technology, Montreal, Canada

Learning to program is known to be very challenging, as evidenced by the low success rates of students in introductory computer science courses observed worldwide. To date, much of the research in programming learning has investigated the learning process by comparing the knowledge and skills of novice and experienced programmers. However, little is known about the early stages of programming learning, which may be a pivotal point in the learning process, as the basic concepts of programming often appear particularly difficult to grasp. Moreover, the role of emotional and cognitive states in programming learning is also under-explored. The current study is the first to investigate the potential relationships between cognitive and emotional states and learning performance in two groups of learners who are at the beginning of their learning process, but differ slightly in their level of programming expertise (12 novices and 11 beginners). Measures of electrodermal activity, automated facial emotion recognition, and pupil diameter were collected while participants performed a sequential programming task for a maximum of 90 minutes on the web platform code.org. We examined (1) how cognitive and emotional states varied with performance during the programming task, and (2) whether participants' expertise (novice or beginner) had a moderating effect on the relationship between cognitive and emotional states and performance. First results of the panel data (n = 690 observations) multiple regression analysis will be presented at the conference. Methodological considerations as well as possible pedagogical implications for learning programming will be discussed.

PERSONALIZED TRANSCRANIAL ELECTRICAL STIMULATION (TES) FOR MODULATION OF ASSOCIATIVE MEMORY PERFORMANCE

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Dunja Paunovic[1], Jovana Bjekić[1], Katarina Vulić[1], Marko Živanović[2], Uroš Konstantinović[1], Marija Stanković[1], Saša Filipović[1]

Associative memory (AM) represents an ability to bind unrelated information into meaningful units and encode them as distinct memories. AM has been the function of interest in many non-invasive transcranial electrical stimulation (tES) studies aiming to maximize the potential for memory modulation by varying stimulation loci, frequency, and amplitude. In the current study, we aimed to capture modulation potential of AM performance when tailoring the stimulation protocols to the individual brain rhythms. By matching the stimulation frequency to the frequency of each subject's AM task induced electrophysiological activity in theta spectrum (4-8 Hz), we developed two types of personalized oscillatory protocols: otDCS and tACS, which we administered alongside the constant tDCS and a sham condition in the single-blind cross-over experiment. To comparatively assess the effects of different tES protocols delivered over the posterior parietal cortex, we tested the recognition and recall ability of the 42 healthy young adults on paired-associate paradigms after each of four conditions. Conditions were administered week-apart in a counterbalanced order. Group level comparisons of each active tES condition against sham did not show differences in AM performance either on recognition or cued-recall. However, data showed variability in performance depending on the task and the outcome measures, which calls for stratified approach in order to test robustness of observed findings. Apart from introducing a novel approach to probing AM with personalized tES, this well-powered, multi-protocol, multi-task and multi-measure study produced a comprehensive dataset that allows exploration of factors that could uncover different patterns in responsiveness to tES.

INFUSIONS OF A DOPAMINE D1 RECEPTOR AGONIST INTO THE PREFRONTAL CORTEX AND APPETITIVE INHIBITORY DISCRIMINATION LEARNING.

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Naana Owusu-Amoah[1], Rebecca Hock[1], Lauren Waite[1], Charlotte Bonardi[1], Carl Stevenson[2], Helen Cassaday[1]
[1]University Of Nottingham, School Of Psychology, Nottingham, United Kingdom, [2]University of Nottingham, School Of Biosciences, Sutton Bonington, United Kingdom

Aims Impaired inhibitory modulation plays a role in the impulsivity seen in many psychiatric disorders, including addiction and schizophrenia. We investigated whether dopaminergic modulation in specific prefrontal cortex sub-regions, prelimbic (PL) and infralimbic (IL), plays a role in the inhibitory modulation of associative learning. Methods We used a dopamine D1 receptor agonist, SKF81297, to assess how dopamine D1 receptor activation affects associative inhibition in male Wistar rats, compared to saline-infused controls. Inhibitory learning was examined using a within-subjects appetitive Pavlovian task (A+/AX-; Waite et al., 2021, doi:10.1016/j.physbeh.2021.113557). After excitatory training, the animals received daily micro-infusions of SKF81297 before inhibitory acquisition and summation sessions; retardation testing was drug-free. Inhibitory discrimination was measured as the ability of the animals to discriminate X as an indicator of no reward. Summation tested the capacity of X to suppress responding to an alternative exciter. Retardation testing examined new excitatory learning to X. Learning was measured as nose-pokes during the different stimuli relative to baseline responding (‘pre-‘), and was analysed using mixed-factorial 2-way-ANOVAs. Results The learning task showed that overall inhibitory discrimination was learnt, evident as reduced responding to AX- compared to A+ over time, and retardation and summation tests confirmed that conditioned inhibition was shown. There was no inhibitory learning difference by infusion group. However, the SKF81297 micro-infusions tended to decrease baseline (pre-) responding. Conclusions There was no evidence that D1 receptor activation in IL or PL sub-regions modulates inhibitory learning. Future studies may focus on alternative receptor subtypes and/or interconnected brain regions.

THE ACTIVITY OF PHOSPHODIESTERASE 4 IN THE DORSAL HIPPOCAMPUS DURING RECONSOLIDATION SUSTAINS FEAR MEMORY OVER TIME

POSTER SESSION 07 - SECTION: ENGRAM MEMORY AND MEMORY CONSOLIDATION

Jeferson Sohn[1], Nathalie Cardoso[1], Jos Prickaerts[2], Cristina Stern[1]
[1]Federal University of Paraná, Department Of Pharmacology, Curitiba, Brazil, [2]Maastricht University, Department Of Psychiatry And Neuropsychology, Maastricht, Netherlands

Upon retrieval, a consolidated memory can become labile and subsequently restabilized by reconsolidation, which engages brain areas such as the dorsal hippocampus (DH). Consolidation and reconsolidation share several mechanisms. In this line, the role of PKA and phosphodiesterase 4 (PDE4) in consolidation is well determined. However, it is scarcely investigated whether PDE4 activity in the DH underlies fear memory reconsolidation. The aim was to evaluate the role of PDE4 in DH in fear memory reconsolidation. Male Wistar rats, with bilateral cannulas aiming the DH and conditioned to a Context, received roflumilast (ROF; PDE4 inhibitor; 9 ng/side) into the DH 5 min after a short retrieval. Groups were tested 1 and 10 days later (TestA1 and TestA2, respectively). Repeated measures ANOVA followed by Newman-Keuls were used for the analysis of results. The ethics committee approved all procedures (#1436). A significant effect of treatment was observed. The treatment with ROF did not change freezing behavior in TestA1, however, a significant reduction of freezing behavior in TestA2 was detected. This effect depended on PKA activity after retrieval and protein synthesis after Test A1. Furthermore, the effect of ROF depended on memory retrieval and exposure to TestA1 one day later. Together, the results suggest that PDE4 activity in the DH after a short memory retrieval is not associated with the reconsolidation process. However, PDE4 activity is important for memory maintenance mechanisms induced by retrieval. In conclusion, our results indicate that the role of PDE4 in the DH during reconsolidation and consolidation is divergent.

DISCRIMINATING MEMORIES OF ITEMS AND SPATIAL LOCATIONS: IS THERE CONTENT-SPECIFIC MNEMONIC SPECIALIZATION IN THE HUMAN MEDIAL TEMPORAL LOBE?

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Zsuzsanna Nemecz[1,2,3], István Homolya[2,4], György Mező[5,6], Attila Keresztes[2,3]
[1]Doctoral School of Psychology, Elte Eötvös Loránd University, Budapest, Hungary, [2]Brain Imaging Centre, Research Centre For Natural Sciences, Eötvös Loránd Research Network, Budapest, Hungary, [3]Institute of Psychology, Elte Eötvös Loránd University, Budapest, Hungary, [4]Institute of Nuclear Techniques, Budapest University Of Technology And Economics, Budapest, Hungary, [5]Wigner Datacenter, Wigner Research Centre For Physics, Eötvös Loránd Research Network, Budapest, Hungary, [6]Konkoly Observatory, Research Centre For Astronomy And Earth Sciences, Eötvös Loránd Research Network, Budapest, Hungary

Decades of dialogue between neuroscience, computational theories, and experimental psychology helped identify candidate neural computations performed by distinct cortical regions in the medial temporal lobe (MTL) that support memory in a similar fashion across several mammalian species, including humans. It is still debated whether these region-specific computations can be differentiated based on content (e.g., item versus spatial information) or rather mnemonic processes (e.g., detailed versus coarse processing). Extant studies with humans often confound content with process and thus cannot distinguish between these theoretical accounts. In this study, we acquired full-brain high-resolution functional MRI images of human participants (n=39) while they performed a memory task. First, they encoded fractal stimuli (items) and their spatial position on the screen (locations), then performed a recognition task that required fine-grained discrimination between previously encountered and novel items or locations. On the group level, the perirhinal cortex, but not the parahippocampal cortex was sensitive to small alterations in the items presented. In contrast, individual differences in parahippocampal activity during encoding predicted subsequent location discrimination performance. Further, we found that individual differences in dentate gyrus-CA3 activity during encoding predicted later discrimination performance for both items and locations. These results suggest that the perirhinal cortex is more involved in detailed memory for items, whereas the parahippocampal cortex is more involved in detailed memory for spatial locations. In contrast, computations in the dentate gyrus-CA3 are independent of content. Taken together, our results support the view that there is content-specific mnemonic specialization of cortical regions within the human MTL.

THE NEURAL CORRELATES OF SPACING

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Michelle Caffrey[1], Seán Commins[2]
[1]Maynooth University, Psychology, Kildare, Ireland, [2]Maynooth University, Dept. Of Psychology, Maynooth, Ireland

Research regarding the neural basis underlying the spacing effect lends support to some of the theories posed to explain the effects of distributed practice. For example, literature indicates extra frontal activity in spaced-trained participants, which may be indicative of deficient processing, and differences in latency of ERP components, which may be indicative of study phase retrieval. In particular, there is limited research examining the electrophysiological correlates of spacing. This study attempted to investigate the neural basis of the spacing effect while learning face-name associations using EEG. The results suggest that there are significant differences between spaced- and massed-trained participants when correctly identifying previously learned face-name pairs. Most notably, spaced participants demonstrate neural activity indicative of greater processing, familiarity, and recognition of stimuli compared to massed participants. Results also provide support for theories of deficient processing and study phase retrieval. These findings may have implications with regard to explaining why spacing is so beneficial.

RESTING-STATE FAST BRAIN DYNAMICS PREDICT INTER-INDIVIDUAL VARIABILITY IN MOTOR PERFORMANCE

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Liliia Roshchupkina[1], Vincent Wens[2], Nicolas Coquelet[2], Xavier De Tiege[1,2], Philippe Peigneux[1]
[1]Universite Libre de Bruxelles (ULB), Psychology And Education Sciences, Brussels, Belgium, [2]CUB Hôpital Erasme, Functional Neuroimaging, Brussels, Belgium

Motor learning (ML) features rapid enhancement during practice then offline post-practice gains with the reorganization of related brain networks. Within the first 5-30 min after the motor task completion, the performance improves (boost period) indicating fast reorganization of neural networks supporting ML. In this project, we aimed at investigating fast transient, sub-second variations in magnetoencephalographic (MEG) network activity in resting-state (RS) before and after ML. We hypothesised that changes in fast neural dynamics might reflect learning-related plasticity mechanisms and/or inter-individual motor variability in performance. Thirty-four young healthy participants underwent a 5-minute Pre-learning RS session within the MEG scanner followed by Finger Tapping Task (FTT) training. The Post-learning RS was assessed 20 min later within the 'boost' time window. Hidden Markov modelling (HMM) of MEG power envelope signals highlighted 8 recurrent topographical states. For State 1 (Frontal/Sensorimotor) and State 2 (Cuneus/Sensorimotor), motor performance levels (i.e., best performance at the end of the learning session) were associated with HMM temporal parameters both in pre- and post-learning resting-state sessions. Additionally, there was a correlation trend between State 6 (Cuneus/Sensorimotor-Frontal) and motor performance in the post-learning session only. However, no association emerged with offline changes in performance. These results suggest a trait-like relationship between spontaneous transient neural dynamics at rest and inter-individual variations in motor abilities. On the other hand, transient RS dynamics seem not to be state-dependent, i.e., modulated by learning experience and reflect neural plasticity, at least on the short timescale. **Keywords: motor learning, motor performance, magnetoencephalography, hidden Markov**

modelling

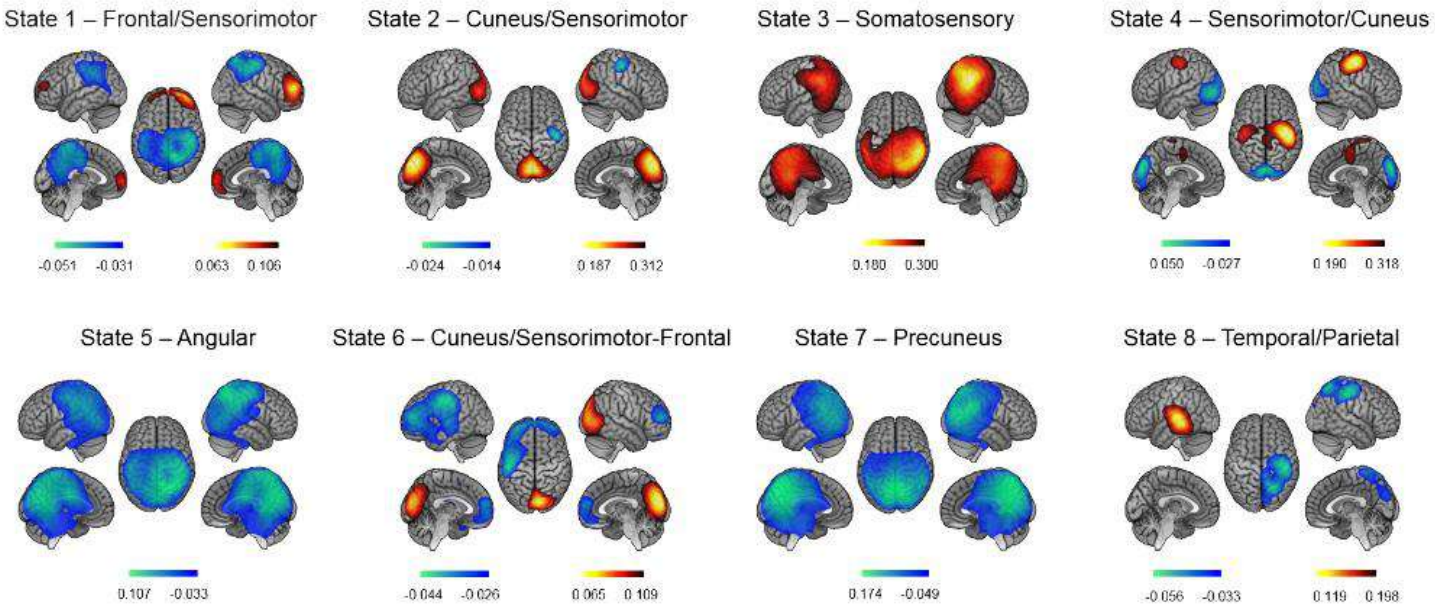

Figure 1. Spatial topographies of HMM transient states computed over pre- and post-learning RS sessions. Red/blue scales indicate positive/negative correlation values between the envelope and the state activation/inactivation time course (i.e., increased/decreased power during one state visit). For visualization purpose, the maps are thresholded between 60 and 100% of the maximum absolute of the partial correlation values.

THE CONTRIBUTION OF THALAMIC SUBDIVISIONS TO LEARNING IS ASSOCIATED WITH INTERINDIVIDUAL VARIABILITY IN MEMORY PERFORMANCE

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Roberta Passiatore[1,2], Linda Antonucci[2], Manojkumar Saranathan[3], Alessandro Bertolino[2], Boris Suchan[4], Giulio Pergola[2,5]
[1]Georgia State University, Tri-institutional Center For Translational Research In Neuroimaging And Data Science (trends), Atlanta, United States of America, [2]University of Bari Aldo Moro, Department Of Medical Science, Neuroscience And Sense Organs, Bari, Italy, [3]University of Arizona, Department Of Medical Imaging, Tucson, United States of America, [4]Ruhr University Bochum, Institute Of Cognitive Neuroscience, Clinical Neuropsychology, Bochum, Germany, [5]Johns Hopkins Medical Campus, Lieber Institute For Brain Development, Baltimore, United States of America

Thalamic functional connectivity (FC) with the executive control network (ECN) varies between pre- and post-encoding resting-state fMRI, interposed by the performance of a memory task. As the thalamus is composed of multiple subdivisions, each belonging to distinct thalamo-cortical circuits possibly competing in cognitive functions, we investigated (i) at the group-level, the differential involvement of thalamic subdivisions with ECN in memory, and (ii) at the individual-level, the variability of such involvement across individuals as a function of memory performance. We extracted published individual ECN maps and the thalamic ROI whose FC with ECN varied as function of memory performance in 28 healthy participants (μ age±SD=26±3; m:f=9:19). We segmented T1 scans through THOMAS deriving thalamic subdivisions (anterior, medial, posterior, lateral). At the group-level, we computed the percentage of overlap between subdivisions and the thalamic ROI, finding that lateral subdivision was mainly represented (70%), followed by anterior (25%), posterior (3%), and medial (2%). At the individual-level, the number of significant voxels in each subdivision from pre- and post-encoding ECN spatial maps ($p<0.05$) was correlated with memory performance across sessions (FDR<0.05). During pre-encoding, performance and the medial subdivision number of voxels were positively associated (pFDR=0.04). During post-encoding, performance and the lateral subdivision number of voxels were positively associated (pFDR=0.008), while performance and the posterior subdivision number of voxels were negatively associated (pFDR=0.05). Findings may suggest that different thalamo-cortical circuits differentially support individual memory performance, with medio-cortical connections potentially playing a preparatory role for better performance, and latero- and posterior-cortical connections differentially supporting post-learning stabilization.

Thalamic connectivity measured with fMRI is associated with a polygenic index predicting thalamo-prefrontal gene co-expression.
The functional connectivity between thalamic medio-dorsal nucleus (MD) and cortical regions, especially the dorsolateral prefrontal cortex (DLPFC), is implicated in attentional processing and is anomalous in schizophrenia, a brain disease associated with polygenic risk and attentional deficits. However, the molecular and genetic underpinnings of thalamic connectivity anomalies are unclear. Given that gene co-expression across brain areas promotes synchronous interregional activity, our aim was to investigate whether coordinated expression of genes relevant to schizophrenia in MD and DLPFC may reflect thalamic connectivity anomalies in an attention-related network including the DLPFC. With this aim, we identified in datasets of post-mortem prefrontal mRNA expression from healthy controls a gene module with robust overrepresentation of genes with coordinated MD-DLPFC expression and enriched for schizophrenia genes according to the largest genome-wide association study to date. To link this gene cluster with imaging phenotypes, we computed a Polygenic Co-Expression Index (PCI) combining single-nucleotide polymorphisms predicting module co-expression. Finally, we investigated the association between PCI and thalamic functional connectivity during attention through fMRI Independent Component Analysis in 265 healthy participants. We found that PCI was positively associated with connectivity strength of a thalamic region overlapping with the MD within an attention brain circuit. These findings identify a novel association between schizophrenia-related genes and thalamic functional connectivity. Furthermore, they highlight the association between gene expression co-regulation and brain connectivity, such that genes with coordinated MD-DLPFC expression are associated with coordinated activity between the same brain regions. We suggest that gene co-expression is a plausible mechanism

underlying biological phenotypes of schizophrenia.

The interaction between OXTR rs2268493 and perceived maternal care is associated with amygdala-dorsolateral prefrontal effective connectivity during explicit emotion processing.
Previous studies have indicated a link between socio-emotional processing and the oxytocin receptor. In this regard, a single nucleotide polymorphism in the oxytocin receptor coding gene (OXTR rs2268493) has been linked with lower social functioning, increased risk for autism spectrum disorders (ASDs) and with post-mortem OXTR mRNA expression levels. Indeed, the levels of expression of OXTR in brain regions involved in emotion processing are also associated with maternal care. Furthermore, maternal care has been associated with emotional correlates. Taken together, these previous findings suggest a possible combined effect of rs2268493 and maternal care on emotion-related brain phenotypes. A crucial biological mechanism subtending emotional processing is the amygdala-dorsolateral prefrontal cortex (DLPFC) functional connection. On this basis, our aim was to investigate the interaction between rs2268493 and maternal care on amygdala-DLPFC effective connectivity during emotional evaluation. We characterized through dynamic causal modeling (DCM) patterns of amygdala-DLPFC effective connectivity during explicit emotion processing in healthy controls (HC), profiled based on maternal care and rs2268493 genotype. In the whole sample, right top-down DLPFC-to-amygdala pattern was the most likely directional model of effective connectivity. This pattern of connectivity was the most likely for all rs2268493/maternal care subgroups, except for thymine homozygous (TT)/low maternal care individuals. Here, a right bottom-up amygdala-to-DLPFC was the most likely directional model. These results suggest a gene by environment interaction mediated by the oxytocin receptor on biological phenotypes relevant to emotion processing.

Multivariate classification of schizophrenia and its familial risk based on load-dependent attentional control brain functional connectivity.
Patients with schizophrenia (SCZ), as well as their unaffected siblings (SIB), show functional connectivity (FC) alterations during performance of tasks involving attention. As compared with SCZ, these alterations are present in SIB to a lesser extent and are more pronounced during high cognitive demand, thus possibly representing one of the pathways in which familial risk is translated into the SCZ phenotype. Our aim is to measure the separability of SCZ and SIB from healthy controls (HC) using attentional control-dependent FC patterns, and to test to which extent these patterns span a continuum of neurofunctional alterations between HC and SCZ. 65 SCZ with 65 age and gender-matched HC and 39 SIB with 39 matched HC underwent the Variable Attentional Control (VAC) task. Load-dependent connectivity matrices were generated according to correct responses in each VAC load. Classification performances of high, intermediate and low VAC load FC on HC-SCZ and HC-SIB cohorts were tested through machine learning techniques within a repeated nested cross-validation framework. HC-SCZ classification models were applied to the HC-SIB cohort, and vice-versa. A high load-related decreased FC pattern discriminated between HC and SCZ with 66.9% accuracy and with 57.7% accuracy between HC and SIB. A high load-related increased FC network separated SIB from HC (69.6% accuracy), but not SCZ from HC (48.5% accuracy). Our findings revealed signatures of attentional FC abnormalities shared by SCZ and SIB individuals. We also found evidence for potential, SIB-specific FC signature, which may point to compensatory neurofunctional mechanisms in persons at familial risk for schizophrenia.

The interaction between cannabis use and a CB1-related polygenic co-expression index modulates dorsolateral prefrontal activity during working memory processing.
Convergent findings indicate that cannabis use and variation in the cannabinoid CB1 receptor coding gene (CNR1) modulate prefrontal function during working memory (WM). Other results also suggest that cannabis modifies the physiological relationship between genetically induced expression of CNR1 and prefrontal WM processing. However, it is possible that cannabis exerts its modifying effect on prefrontal physiology by interacting with complex molecular ensembles co-regulated with CB1. Since co-regulated genes are likely co-expressed, we investigated how genetically predicted co-expression of a molecular network including CNR1 interacts with cannabis use in modulating WM processing in humans. Using post-mortem human prefrontal data, we first computed a polygenic score (CNR1-PCI), combining the effects of single nucleotide polymorphisms (SNPs) on co-expression of a cohesive gene set including CNR1, and positively correlated with such co-expression. Then, in an in vivo study, we computed CNR1-PCI in 88 cannabis users and 147 non-users and investigated its

interaction with cannabis use on brain activity during WM. Results revealed an interaction between cannabis use and CNR1-PCI in the dorsolateral prefrontal cortex (DLPFC), with a positive relationship between CNR1-PCI and DLPFC activity in cannabis users and a negative relationship in non-users. Furthermore, DLPFC activity in cannabis users was positively correlated with the frequency of cannabis use. Taken together, our results suggest that co-expression of a CNR1-related network predicts WM-related prefrontal activation as a function of cannabis use. Furthermore, they offer novel insights into the biological mechanisms associated with the use of cannabis.

How recent learning shapes the brain: Memory-dependent functional reconfiguration of brain circuits.
The process of storing recently encoded episodic mnestic traces so that they are available for subsequent retrieval is accompanied by specific brain functional connectivity (FC) changes. In this fMRI study, we examined the early processing of memories in twenty-eight healthy participants performing an episodic memory task interposed between two resting state sessions. Memory performance was assessed through a forced-choice recognition test after the scanning sessions. We investigated resting state system configuration changes via Independent Component Analysis by cross-modeling baseline resting state spatial maps onto the post-encoding resting state, and post-encoding resting state spatial maps onto baseline. We identified both persistent and plastic components of the overall brain functional configuration between baseline and post-encoding. While FC patterns within executive, default mode, and cerebellar circuits persisted from baseline to post-encoding, FC within the visual circuit changed. A significant session × performance interaction characterized medial temporal lobe and prefrontal cortex FC with the visual circuit, as well as thalamic FC within the executive control system. Findings reveal early-stage FC changes at the system-level subsequent to a learning experience and associated with inter-individual variation in memory performance.

ON THE IMPORTANCE OF HIPPOCAMPAL SEGMENTATION FOR THE NEURAL MAPPING OF MEMORY: EVIDENCE FROM A LARGE-SCALE STUDY OF NEURAL ARCHITECTURE IN HEALTHY ADULTS

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Katarina Vulić[1], Claude Bajada[2], Dunja Paunovic[1], Jovana Bjekić[1], Saša Filipović[1], Kristian Sandberg[3]

The hippocampus (HC) is traditionally considered the key neuroanatomical hub responsible for memory. However, previous MRI studies that aimed to relate volumetric hippocampal measures to associative memory (AM) performance have yielded mixed results. In the current study, we aimed to reevaluate these findings in a large sample of young healthy participants (N = 246; age M = 24.95, SD = 4.58; 56% female). Participants were scanned with 3T MAGNETOM Prisma using a 64-channel head coil, followed by the AM assessment in the lab setting. To maximize the scope of AM assessment, we employed four paired-associate tasks of various stimuli modalities (faces, words, scenes) and outcome measure types (recognition, recall). Synthetic T1-weighted images were produced out of relaxometry parameter maps, after which volumetric measures were calculated using FreeSurfer. The whole HC volume showed no correlation with any of the memory measures. However, further segmentation of HC into its functional and anatomical subfields (Parasubiculum, Presubiculum, Subiculum, CA1, CA2/3, CA4, GC-DG, HATA, Fimbria, Molecular layer, Hippocampal fissure, Hippocampal tail) showed scattered yet consistent patterns of significant correlations between different subfield volumes and memory outcomes. The results suggest that distinctive contributions of HC subfields may lead to a null effect when the whole HC volume is considered, thus demonstrating that drawing conclusions based on the volumetric measures of neural macrostructures can be misleading. The results highlight the importance of in-depth segmentation for neural mapping.

MOTOR-SENSORY DYNAMICS DURING MEMORY ENCODING AND RECALL

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Neomi Mizrachi[1], Ehud Ahissar[2]
[1]Weizmann institute of science, Brain Sciences, Rehovot, Israel, [2]Weizmann Institute of science, Brain Sciences, Rehovot, Israel

Motor-sensory dynamics is an essential component of perception. During an episode, the scanning patterns of sensory organs affect the acquired information. Despite that, the inter-relations between motor-sensory dynamics and episodic memory are not often studied. To fill this gap, we designed a free recall task that took place in a virtual reality (VR) environment, in which participants could freely move. During the encoding stage, participants were asked to explore a VR environment containing 15 everyday virtual objects. During the recall stage, participants were asked to recall the objects' names in a different VR environment. Participants' eyes, hands and heads were tracked at both stages. During encoding, participants walked around, looked at (virtual) objects and sometimes moved objects (virtually). Our results suggest that two motor-sensory factors occurring during encoding could increase objects' recall probability: The action of moving an object and the total gazing time at an object. The order of objects' recall was correlated with the order of their locations along the walking trajectory during encoding but not with the order in which they were gazed at. Participants who recalled in an environment that resembled the encoding environment tended to perform longer and slower drifts during recall. These initial results already point to specific roles played by motor-sensory dynamics in memory encoding and recall.

How do creative ideas arise? A common assumption is that ideas result from searching and combining semantic memory knowledge. However, the mechanisms acting on memory to yield creative ideas are not elucidated. This study explores the neurocognitive correlates of semantic search components related to creative abilities. We designed an associative fluency task based on polysemous words. We distinguished two search components by assessing clustering and switching performance from the responses within and between the different meanings. We related these components to creativity, executive abilities, and semantic memory structure explored with semantic networks methods, and identified their predictive functional brain connectivity patterns using connectome-based modeling. Clustering correlated with divergent thinking, while switching correlated with the ability to combine remote associates. Furthermore, switching correlated with semantic memory structure and executive abilities, and was predicted by connectivity between and within the default, control, and salience networks. These results suggest that switching captures interactions between memory structure and control processes guiding the search. In contrast, clustering relied on interactions between control, salience, and attentional networks. Clustering may capture controlled processes related to persistent search. These findings shed new light on the neurocognitive mechanisms allowing an efficient and flexible semantic search to support creativity.

THE N400 AS A NEUROPHYSIOLOGICAL MARKER OF SECOND-LANGUAGE LEARNING

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Nicole Skieresz[1,2], Sandy Marca[1,3], Simon Gorin[1], Thomas Reber[1,4], Nicolas Rothen[1]
[1]Uni Distance Swiss, Faculty Of Psychology, Brig, Switzerland, [2]University of Lausanne, Faculty Of Biology And Medicine, Lausanne, Switzerland, [3]University of Geneva, Faculty Of Psychology, Geneva, Switzerland, [4]University of Bonn Medical Center, Department Of Epileptology, Bonn, Germany

Research on memory has identified various learning principles to support knowledge acquisition. Some of the most effective learning principles are retrieval practice (i.e., actively recalling information), multimodal learning (i.e., presenting information via multiple sensory modalities), and corrective feedback (i.e., receiving the correct response when making an error). While each learning principle has been examined separately, interactions between them and their underlying neurophysiological correlates remain to be investigated. Thus, our study aims to investigate potential interactions between the learning principles on associative memory (i.e., vocabulary acquisition) and their neurophysiological correlates. Healthy young adults learned Finnish vocabulary for 14 days using the mobile phone application “stellar-learning”, thereby manipulating the proportion of retrieval, multimodality, and feedback on an individual word basis. Before and after the learning intervention, participants performed a cross-language priming task, where they were asked to identify congruent and incongruent collocations (i.e., native language and learnt Finnish vocabulary), while their EEG was recorded. We assessed the correctness of responses and compared the N400 event-related brain potentials component – a marker for semantic violations – for congruent and incongruent associations by learning principle. We hypothesized a larger N400 amplitude for incongruent than congruent collocations after learning, but not before. Moreover, we expected this effect to be modulated by combinations of different learning principles. Preliminary results show an increase in proportion of correct responses and indicate a modulation in the N400 window on the level of the learning principles after learning. These results suggest that learning can be optimized by combining learning principles.

THE HIPPOCAMPUS CONSTRUCTS SEQUENCE MEMORIES THAT GENERALIZE TEMPORAL RELATIONS ACROSS EXPERIENCES

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Jacob Bellmund[1], Lorena Deuker[2], Nicole Montijn[3], Christian Doeller[1,4]
[1]Max Planck Institute for Human Cognitive and Brain Sciences, Psychology, Leipzig, Germany, [2]Radboud University, Donders Institute For Brain, Cognition, And Behaviour, Nijmegen, Netherlands, [3]Utrecht University, Department Of Clinical Psychology, Utrecht, Netherlands, [4]Norwegian University of Science and Technology, Kavli Institute For Systems Neuroscience,, Trondheim, Norway

The hippocampal-entorhinal region supports memory for episodic details, such as temporal relations of sequential events, and mnemonic constructions combining experiences for inferential reasoning. However, it is unclear whether hippocampal event memories reflect temporal relations derived from mnemonic constructions, event order, or elapsing time, and whether these sequence representations generalize temporal relations across similar sequences. Here, participants mnemonically constructed times of events from multiple sequences using infrequent cues and their experience of passing time. After learning, event representations in the anterior hippocampus reflected temporal relations based on constructed times. Temporal relations were generalized across sequences, revealing distinct representational formats for events from the same or different sequences. Structural knowledge about time patterns, abstracted from different sequences, biased the construction of specific event times. These findings demonstrate that mnemonic construction and the generalization of relational knowledge combine in the hippocampus, consistent with the simulation of scenarios from episodic details and structural knowledge.

In this study, we asked whether functional interaction or structural defects in the right Crus I cerebellum, such as those highlighted in ASD mouse models and in young ASD individuals, could be observed in adults and have an impact outside the range of social deficits and repetitive behaviors, namely in navigation. Knowing the role of RCrus I-prefrontal connectivity in sequence-based navigation, which relies on memorizing a route, we expected that participants with ASD might have deficits in learning and executing this strategy, and be biased toward the use of another strategy when free to do so. On the other hand, the literature suggesting difficulties with place learning relying on allocentric representations, we also anticipated participants to underperform place-based strategy. We therefore tested adults with ASD or typical development in a navigation task, using the virtual Starmaze environment which allows us to assess the ability to use each of these strategies. We thus compared learning, strategy preferences and performances, as well as memories of the environment after the task. In parallel, participants underwent structural and functional MRI at rest, allowing us to study the volume and connectivity of Crus I in the same sample of subjects. Surprisingly but interestingly, despite the involvement of RCrus I in navigation, and its described involvement in ASD, we observed neither behavioral deficits, nor alterations in RCrusI volume or connectivity in our sample of participants.

VISUOSPATIAL PERSPECTIVE-TAKING-SPECIFIC BRAIN DYNAMICS CAPTURED BY IEEG

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Anna Gunia[1,2], Sofiia Moraresku[1,2], Iveta Fajnerová[1], Tereza Nekovářová[1], Jiri Hammer[3], Adam Kalina[3], Petr Marusič[3], Kamil Vlček[1]
[1]Institute of Physiology, Czech Academy of Sciences, Laboratory Of Neurophysiology Of Memory, Prague, Czech Republic, [2]Charles University, 3rd Faculty Of Medicine, Prague, Czech Republic, [3]Charles University in Prague, 2nd Faculty of Medicine, University Hospital Motol, Department Of Neurology, Prague, Czech Republic

Visuospatial perspective-taking (VPT) requires overcoming self-perspective and imagining a scene from another perspective. It is essential for spatial and social reasoning. Studies outline brain areas involved in VPT; however, they largely overlap with self-perspective. To separate VPT from self-perspective brain activity, it is vital to estimate when and where the responses only to VPT but not to self-perspective emerge. Therefore, first, we aimed to spatiotemporally differentiate the brain responses only to VPT (VPT-specific) from the responses only to self-perspective (Self-specific), and responses to both perspectives (General). Hierarchical processing theory suggests that stimulus-specific responses emerge over time. Considering this, our second aim was to test the hypothesis whether task-condition-specific (VPT-specific, Self-specific) responses start later than General responses. We recorded iEEG data from 30 patients with pharmacoresistant epilepsy. The patients performed a VPT task requiring laterality judgments from self or another perspective. We estimated the spatiotemporal features of responses with Time-Frequency analysis in the broad gamma band (50–150 Hz). From 10 regions of interest (ROI), the parietal and medial temporal lobe, lateral prefrontal cortex, and insula exhibited all types of responses (VPT-specific, Self-specific, General). The rest of the ROIs showed VPT-specific and General responses. VPT-specific and Self-specific responses had similar dynamics. In contrast, task-condition-specific responses started later and lasted shorter than General responses. Our results anatomically differentiate VPT-specific responses from Self-specific and temporally from General responses. Additionally, we give a novel example of hierarchical processing, showing that task-condition-specific processing starts later and lasts shorter than general processing. Supported by GACR:19-11753S; RVO:67985823.

Brain mechanisms of visuospatial perspective-taking in relation to object mental rotation and the theory of mind.
Visuospatial perspective-taking (VPT) is a process of imagining what can be seen and how a scene looks from a location and orientation in space that differs from one's own. It comprises two levels that are underpinned by distinct neurocognitive processes. Level-2 VPT is often studied in relation to two other cognitive phenomena, object mental rotation (oMR) and theory of mind (ToM). With the aim to describe the broad picture of neurocognitive processes underlying level-2 VPT, here we give an overview of the recent behavioral and neuroscientific findings of level-2 VPT. We discuss its relation to level-1 VPT, which is also referred to as perspective-tracking, and the neighboring topics, oMR and ToM. Neuroscientific research shows that level-2 VPT is a diverse cognitive process, encompassing functionally distinct neural circuits. It shares brain substrates with oMR, especially those parietal brain areas that are specialized in spatial reasoning. However, compared to oMR, level-2 VPT involves additional activations in brain structures that are typically involved in ToM tasks and deal with self/other distinctions. In addition, level-2 VPT has been suggested to engage brain areas coding for internal representations of the body. Thus, the neurocognitive model underpinning level-2 VPT can be understood as a combination of visuospatial processing with social cognition and body schema representations.

FUNCTIONAL IMPLICATIONS OF VERTICAL CODING BIASES IN SCENE-SELECTIVE REGIONS ON SPATIAL ORIENTATION: EVIDENCE FROM SOURCE LOCALIZED EEG RECORDINGS.

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Alexandre Delaux[1], Marion Durteste[1], Ainhoa Ariztégui[1], Bilel Benziane[1], Benoit R. Cottereau[2,3], Stephen Ramanoël[1,4], Angelo Arleo[1]
[1]Sorbonne Université, INSERM, CNRS, Institut De La Vision, Paris, France, [2]Université de Toulouse, Centre De Recherche Cerveau Et Cognition, Toulouse, France, [3]Centre National de la Recherche Scientifique, Cnrs, Toulouse, France, [4]Université Côte d'Azur, Lamhess, Nice, France

Aims: fMRI studies identified scene-selective brain regions (namely: Parahippocampal place area – PPA; Retrosplenial cortex – RSC; Occipital place area – OPA) involved in the recognition and processing of visual scenes. Recent findings showed that these regions exhibit distinct retinotopic preferences for either the upper or lower visual field. Given their visuo-spatial function, we hypothesized that the vertical location of visual information useful for orientation would influence the activity of scene-selective regions. **Methods**: Twenty-four young adults (28 ± 4.9 y.o.) took part in a desktop-based virtual reality task. Subjects had to learn how to orient within a four-intersection environment, using landmarks that were only visible at the intersections. Landmarks that carried navigational information were positioned either in the lower or the upper part of the screen. We collected behavioral, eye-tracking, and EEG data. Using an individualized source reconstruction model, we extracted the electrical activity imputable to each scene-selective region. **Results**: The vertical position of the navigationally useful landmarks did not impact task performance. However, at the neural level, it modulated the activity of scene-selective regions when processing visual information at intersections. Vertical properties of scenes thus seem to impact higher-level integration of spatial information. **Conclusions**: As the nature of visual information varies significantly along the vertical axis in everyday environments, the reported evidence underlines the possibility that retinotopic preferences in higher visual areas emerged to serve complex cognitive abilities such as spatial navigation.

EXAMINING OVERSHADOWING IN HEALTHY ADULTS USING A VIRTUAL MAZE TASK.

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Roisin Deery
Maynooth University, Psychology, Leixlip, Co.Kildare, Ireland

Aims Previous research in the area of spatial navigation has suggested that humans use a cognitive map to navigate their surroundings, but there may be a simpler explanation via associative learning theory (Pearce, 2009). Overshadowing is a phenomenon underpinning associative learning theories in which learning about a cue is reduced when it is accompanied by a second cue during learning. This has been observed in previous research outside of the spatial domain and in animal studies. This experiment aims to investigate whether overshadowing also occurs during human spatial learning. **Methods** NavWell, a virtual Morris Water Maze was used to investigate evidence for overshadowing in young healthy adult participants (aged 18-24). Five groups (n=25/group) were used. Groups 1 and 2 were trained with two cues, one near and one far from the goal, and then tested on one cue respectively. Group 3 was trained and tested with both cues. Group 4 was trained and tested with the far cue only, and Group 5 was trained and tested with the near cue only. **Results** Overall findings indicated that those trained with both cues and retested with a single cue (i.e., Groups 1& 2) performed significantly worse than those trained and tested with a single cue (irrespective of cue location, Groups 4 & 5), suggesting a possible overshadowing effect in healthy human participants. **Conclusions** These findings support animal literature and suggest that spatial learning is associative, providing a more parsimonious explanation for how humans navigate than that proposed by cognitive map theory.

COGNITIVE SKILLS RELATED TO NAVIGATION IN CHILDREN FROM 6 TO 11 YEARS OLD.

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Cindy Oceánida Zurita Bautista, Irma Del Río Portilla, Gustavo David Ortiz Lagunes
Universidad Nacional Autónoma de México, Laboratorio De Sueño, Facultad De Psicología, Ciudad de México, Mexico

Cognitive mapping includes different cognitive and perceptual skills. The map formation process can be differentiated in the coding and recall of landmarks. Currently, there is no consensus regarding the skills required for each of these phases. The objective of the present study was to analyze the relationship of perceptual, memory, spatial and executive abilities in the encoding and recall of landmarks in a group of 11 children aged 6 to 11 years with typical development. We administered the Wechsler Intelligence Scale WISC-4, the Neuropsychological Evaluation for Children (ENI-2, acronym in Spanish), the Porteous Maze, and a virtual-navigation task. We analyzed the relationship between the scores obtained in the evaluation with the performance in the encoding and recall navigation tasks using Spearman's r correlation coefficient. We observed that the average distance navigated correlates positively with the performance in the identification of the orientation of lines (OL) and location of coordinates (UC); both in the encoding (OL, $r=0.671$ $p<0.05$; and UC, $r= 0.688$). $p<0.01$) as well as recall (OL, $r=0.613$ $p<0.05$; and UC, $r= 0.793$ $p<0.01$) tasks. We also observed differential cognitive functions and processes depending on the process of landmark encoding or recall. We propose that cognitive processes associated with navigation are differential. These are related on the phase of the formation of the cognitive map. Perceptual processes participate in encoding; while the activation and manipulation of representations stored in memory are demanded during landmark´s recall. **Acknowledgments** CONACYT Beca de Doctorado CVU 409832 DGAPA Proyect IN231720.

EGOCENTRIC AND ALLOCENTRIC TEMPORAL COGNITIVE MAPS

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Anna Wagelmans, Virginie Van Wassenhove
Cognitive Neuroimaging Unit, Inserm, Cea, Cnrs, Université Paris-saclay, Neurospin Center, Gif-sur-Yvette, France

Through "mental time travel", humans can project themselves in time, reliving past events or exploring possible future outcomes. This ability requires that events be flexibly mapped on an internal temporal coordinate system. Personal and world events can be mapped relative to the self, constructing an egocentric map. Conversely, fictional events would be mapped on a landmark-based allocentric map. In both allocentric and egocentric representations, self-projection in mental time travel can be operationalized as a shift of the temporal map on a new reference. We expected that the behavioural cost (as assessed by measures of reaction times) of this shift would parametrically increase with the distance of projection. In a series of psychophysics experiments, participants projected themselves at different distances in the past and in the future and performed temporal order judgments on given events. The events were either historical (N = 31) or fictional (N = 24), characterizing respectively the egocentric and the allocentric map. Though we find no clear increase of the behavioural cost along distance of projection, we identified confounds in the experimental design. To correct for these, a new series of experiments is being conducted.

To investigate the age effect on spatial navigation, we used a virtual task, the "Apple Game", distinguishing between landmark-based and pure path integration. Participants navigated in a virtual field. They had to pick up a basket, find an apple in a tree and drop back the basket to its initial location. Difficulty varied according to the number of interim locations (trees) and the presence/absence of a landmark. We recruited 400 volunteers from four European centers. Linear mixed models predicted the drop error with age. Then, we predicted the traveled distance (distance apple-drop location) and the angle realized (apple-landmark-drop location) to understand the mechanisms leading to navigational errors (Fig. 1). The drop error increased with age and decreased with the landmark. The landmark effect decreased with age. For older participants, the traveled distance depended on the initial view of the basket (distance start-basket) and not on the correct distance to travel (distance apple-goal location). Furthermore, the angle realized depended on the initial view (angle start-landmark-basket) and not on the correct angle (angle apple-landmark-goal location). Younger participants were able to navigate without bias toward the initial view. In conclusion, landmark-based navigation decreases with age. Elderly participants were biased toward the initial view and did not integrate their position with the landmark

location.

BRAIN ACTIVITY IN ENCODING OF EXPLICIT SEQUENTIAL VISUOSPATIAL MEMORY

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Milena Mihovilovic, Thomas Eggert, Thomas Stephan, Marianne Dieterich, Andreas Straube
Ludwig-Maximilians-Universität München University Hospital, Department Of Neurology, Munich, Germany

Repeated presentation of long visuospatial sequences incrementally commits their content to episodic memory, with the transfer from working memory taking place over specific timespans of encoding. Using fMRI (3T, n=29), we sought to identify the brain regions recruited during this form of learning. Presentation trials of a 20-target long learning paradigm alternated with recall periods whose behavioral data (captured by eye-tracking) was used to determine encoding progress as a function of time during presentation. This encoding progress was used as a continuous predictor of BOLD activity. To isolate activity specifically related to learning as opposed solely to attentional shifts, a second, purely attentional task was devised, with an analogous temporal structure to the encoding periods. Investigating the coefficient of a general linear model fitting BOLD activity as a function of the learning or attention predictor, significant activity was shown for both predictors in the bilateral superior frontal gyri, superior parietal lobules, and middle temporal gyri. To investigate whether these areas were specifically involved in learning, independent from simultaneous attentional control, we performed a repeated measures ANOVA, revealing significant interactions between region and experiment as well as hemisphere and experiment. While attentional activation did not differ between regions, learning activation was stronger in the superior parietal lobules and middle temporal gyri than superior frontal gyri. These preliminary findings suggest the superior parietal lobule and middle temporal gyrus, but not superior frontal gyrus, are specifically involved in the acquisition of long-term spatial memory.

TIMING OF ALLOCENTRIC AND EGOCENTRIC SPATIAL CODING REVEALED BY HUMAN INTRACRANIAL EEG

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Sofiia Moraresku[1,2], Anna Gunia[1,2], Jiri Hammer[3], Adam Kalina[3], Petr Marusič[3], Kamil Vlček[1]
[1]Institute of Physiology, Czech Academy of Sciences, Laboratory Of Neurophysiology Of Memory, Prague, Czech Republic, [2]Charles University, 3rd Faculty Of Medicine, Prague, Czech Republic, [3]Charles University in Prague, 2nd Faculty of Medicine, University Hospital Motol, Department Of Neurology, Prague, Czech Republic

Taking advantage of the high temporal resolution of intracranial EEG (iEEG), we aimed to establish precise timing of egocentric and allocentric information processing and clarify involved brain areas. Although many fMRI studies have focused on studying the brain areas associated with egocentric and allocentric coding, their results are not always consistent. Moreover, they lacked the temporal dynamic of involved cognitive processes. We developed a task requiring a fast spatial decision using allocentric or egocentric spatial coding in the three-dimensional virtual arena. The task for subjects was to estimate which of two goals on the arena floor was closer to a specific landmark or themselves, respectively. We recorded iEEG data from 37 drug-resistant epilepsy patients and analyzed broadband gamma activity (50–150Hz). We found channels responding to both egocentric and allocentric conditions in many brain regions, with their highest number in the frontal cortex. Egocentric-selective channels were mainly found in the lingual and supramarginal gyri. In the lingual gyrus, the egocentric response was higher than the allocentric one at the time window 300-1000 ms. Allocentric-selective channels were found around the intraparietal sulcus and in the occipital and lateral temporal cortex. In the intraparietal sulcus, the difference between allocentric and egocentric responses was observed at 400-700 ms after stimulus onset, while in the occipital and lateral temporal cortex, it emerged later, at 600-700 ms. Our findings suggest that egocentric and allocentric coding relies on overlapping but partially distinct neural mechanisms with a different temporal processing scheme. *supported by GACR 19-11753S and RVO: 67985823*

WHEN HUMANS LIVE ON A SMALL PLANET: SPATIAL MEMORY AND PATH INTEGRATION ON A SPHERICAL SURFACE

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Misun Kim[1], Christian Doeller[1,2]
[1]Max Planck Institute for Human Cognitive and Brain Sciences, Department Of Psychology, Leipzig, Germany, [2]NTNU, Kavli Institute For Systems Neuroscience, Trondheim, Norway

Humans can build cognitive maps of the world. The nature of the cognitive map, relying on fundamental neural coding principles in the hippocampal formation, would be influenced by the environment, and most people live on a surface that can be best described with Euclidean geometry. Whether people can adapt and build a map for a novel environment in which they can no longer rely on Euclidean geometrical intuition is an intriguing question that can help us to understand the capacity and limitation of human cognition. To answer this question, we designed a study where participants explore the planar and spherical world on separate days using a virtual reality treadmill. They first learned a spatial layout of objects and were tested of their object-location memory, and then they completed a path integration task, known as the triangle completion test. Preliminary data analysis shows that participants were similarly good at locating objects on both plane and sphere, suggesting a remarkable capacity in learning an unfamiliar map structure. However, in the path integration task, they showed a systematic overturn bias on the sphere, as a consequence of following the Euclidean geometrical rule on the non-Euclidean surface. This result implies a strong Euclidean geometrical prior in human mind despite the capacity of building a map for a non-flat surface, and can inform future neuroscientific investigations of the cognitive map.

Encoding of 3D head direction information in the human brain.
Head direction cells are critical for navigation because they convey information about which direction an animal is facing within an environment. To date, most studies on head direction encoding have been conducted on a horizontal two-dimensional (2D) plane, and little is known about how three-dimensional (3D) direction information is encoded in the brain despite humans and other animals living in a 3D world. Here, we investigated head direction encoding in the human brain while participants moved within a virtual 3D "spaceship" environment. Movement was not constrained to planes and instead participants could move along all three axes in volumetric space as if in zero gravity. Using functional magnetic resonance imaging (fMRI) multivoxel pattern similarity analysis, we found evidence that the thalamus, particularly the anterior portion, and the subiculum encoded the horizontal component of 3D head direction (azimuth). In contrast, the retrosplenial cortex was significantly more sensitive to the vertical direction (pitch) than to the azimuth. Our results also indicated that vertical direction information in the retrosplenial cortex was significantly correlated with behavioral performance during a direction judgment task. Our findings represent the first evidence showing that the "classic" head direction system that has been identified on a horizontal 2D plane also seems to encode vertical and horizontal heading in 3D space in the human brain.

Can we study 3D grid codes non-invasively in the human brain? Methodological considerations and fMRI findings.
Recent human functional magnetic resonance imaging (fMRI) and animal electrophysiology studies suggest that grid cells in entorhinal cortex are an efficient neural mechanism for encoding knowledge about the world, not only for spatial location but also for more abstract cognitive information. The world, be it physical or abstract, is often high-dimensional, but grid cells have been mainly studied on a simple two-dimensional (2D) plane. Recent theoretical studies have proposed how grid cells encode three-dimensional (3D) physical space, but it is unknown whether grid codes can be examined non-invasively in humans. Here, we investigated whether it was feasible to test different 3D grid models using fMRI based on the direction-modulated property of grid signals. In doing so, we developed interactive software to help researchers visualize 3D grid fields and predict grid activity in 3D as a function of movement directions. We found that a direction-modulated grid analysis was sensitive to one type of 3D grid model - a face-centred cubic (FCC) lattice model. As a proof of concept, we searched for 3D grid-like signals in human entorhinal cortex using a novel 3D virtual reality paradigm and a new fMRI analysis method. We

found that signals in the left entorhinal cortex were explained by the FCC model. This is preliminary evidence for 3D grid codes in the human brain, notwithstanding the inherent methodological limitations of fMRI. We believe that our findings and software serve as a useful initial stepping-stone for studying grid cells in realistic 3D worlds and also, potentially, for interrogating abstract high-dimensional cognitive processes.

Hippocampus, Retrosplenial and Parahippocampal Cortices Encode Multicompartment 3D Space in a Hierarchical Manner.
Humans commonly operate within 3D environments such as multifloor buildings and yet there is a surprising dearth of studies that have examined how these spaces are represented in the brain. Here, we had participants learn the locations of paintings within a virtual multilevel gallery building and then used behavioral tests and fMRI repetition suppression analyses to investigate how this 3D multicompartment space was represented, and whether there was a bias in encoding vertical and horizontal information. We found faster response times for within-room egocentric spatial judgments and behavioral priming effects of visiting the same room, providing evidence for a compartmentalized representation of space. At the neural level, we observed a hierarchical encoding of 3D spatial information, with left anterior hippocampus representing local information within a room, while retrosplenial cortex, parahippocampal cortex, and posterior hippocampus represented room information within the wider building. Of note, both our behavioral and neural findings showed that vertical and horizontal location information was similarly encoded, suggesting an isotropic representation of 3D space even in the context of a multicompartment environment. These findings provide much-needed information about how the human brain supports spatial memory and navigation in buildings with numerous levels and rooms.

Multivoxel Pattern Analysis Reveals 3D Place Information in the Human Hippocampus.
The spatial world is three dimensional (3D) and humans and other animals move both horizontally and vertically within it. Extant neuroscientific studies have typically investigated spatial navigation on a horizontal 2D plane, leaving much unknown about how 3D spatial information is represented in the brain. Specifically, horizontal and vertical information may be encoded in the same or different neural structures with equal or unequal sensitivity. Here, we investigated these possibilities using fMRI while participants were passively moved within a 3D lattice structure as if riding a rollercoaster. Multivoxel pattern analysis was used to test for the existence of information relating to where and in which direction participants were heading in this virtual environment. Behaviorally, participants had similarly accurate memory for vertical and horizontal locations and the right anterior hippocampus (HC) expressed place information that was sensitive to changes along both horizontal and vertical axes. This is suggestive of isotropic 3D place encoding. In contrast, participants indicated their heading direction faster and more accurately when they were heading in a tilted-up or tilted-down direction. This direction information was expressed in the right retrosplenial cortex and posterior HC and was only sensitive to vertical pitch, which could reflect the importance of the vertical (gravity) axis as a reference frame. Overall, our findings extend previous knowledge of how we represent the spatial world and navigate within it by taking into account the important third dimension. The spatial world is 3D. We can move horizontally across surfaces, but also vertically, going up slopes or stairs. Little is known about how the brain supports representations of 3D space. A key question is whether horizontal and vertical information is equally well represented. Here, we measured fMRI response patterns while participants moved within a virtual 3D environment and found that the anterior hippocampus (HC) expressed location information that was sensitive to the vertical and horizontal axes. In contrast, information about heading direction, found in retrosplenial cortex and posterior HC, favored the vertical axis, perhaps due to gravity effects. These findings provide new insights into how we represent our spatial 3D world and navigate within it.

Verbal Paired Associates and the Hippocampus: The Role of Scenes.
It is widely agreed that patients with bilateral hippocampal damage are impaired at binding pairs of words together. Consequently, the verbal paired associates (VPA) task has become emblematic of hippocampal function. This VPA deficit is not well understood and is particularly difficult for hippocampal theories with a visuospatial bias to explain (e.g., cognitive map and scene construction theories). Resolving the tension among hippocampal theories concerning the VPA could be important for leveraging a fuller understanding of hippocampal function. Notably, VPA tasks typically use high imagery concrete words and so conflate imagery and binding. To determine why VPA engages the hippocampus, we devised an fMRI encoding task involving closely matched pairs of scene words, pairs of object words, and pairs of very low imagery abstract words. We found that the anterior hippocampus was engaged during processing of both scene and object word pairs in comparison to abstract word pairs, despite binding occurring in all conditions. This was also the case when just subsequently remembered stimuli were considered. Moreover, for object word pairs, fMRI activity patterns in anterior hippocampus were more similar to those for scene imagery than object imagery. This was especially evident in participants who were high imagery users and

not in mid and low imagery users. Overall, our results show that hippocampal engagement during VPA, even when object word pairs are involved, seems to be evoked by scene imagery rather than binding. This may help to resolve the issue that visuospatial hippocampal theories have in accounting for verbal memory.

PRELIMINARY EVIDENCE FOR A ROLE OF COGNITIVE MAPS IN ACTION REPRESENTATION

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Irina Barnaveli[1], Daniel Reznik[1], Patrick Haggard[2], Christian Doeller[1]
[1]Max Planck Institute for Human Cognitive and Brain Sciences, Department Of Psychology, Leipzig, Germany, [2]Institute of Cognitive Neuroscience, University College London, London, United Kingdom

In our everyday life, we often need to execute complex goal-directed actions. To successfully carry them out, it is essential to represent the knowledge about their potential environmental or bodily outcomes. Recent evidence suggests that cognitive maps supported by the hippocampal-entorhinal system organize knowledge in abstract low-dimensional spaces. The goal of this project is to investigate whether the brain can conceptually organize different action plans using a two-dimensional mapping of expected action-outcomes. In particular, we examine if and how the anticipated outcomes of action plans could be used to abstractly represent and flexibly choose between different plans along outcome dimensions. We designed a set of behavioral tasks using immersive VR with HMD and hand controllers. Participants are trained to execute different action sequences, that trigger launching of a ball towards them, and learn to associate those sequences with different probabilities to catch the ball (axis 1), and for the ball to disappear (axis 2). Then, participants compare the sequences based on the learned action-outcome contingencies. We performed multidimensional scaling on the behavioral data from the comparison task and our preliminary results suggest a map-like representation of action sequences. To explore the neural mechanisms of this map-like representation, we will acquire fMRI data in a new study using this paradigm. We hypothesize that encoding mechanisms in hippocampal-entorhinal and parietal-premotor regions are involved in the construction of such a map, thus, supporting behavioral planning by encoding multiple relationships between different action plans, and allowing efficient action selection using a common representational format.

THE HUMAN HIPPOCAMPAL LONG AXIS SHOWS DISCRETE FUNCTIONAL ORGANIZATION DURING SPATIAL NAVIGATION

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Stian Framvik[1], Sabine Huber[2], Koen Haak[3], Asgeir Kobro-Flatmoen[2], Jens Schwarzbach[4], Menno Witter[2], Christian Doeller[5], Tobias Navarro Schröder[2]
[1]NTNU, Kavli Institute For Systems Neuroscience, TRONDHEIM, Norway, [2]NTNU, Kavli Institute For Systems Neuroscience, Trondheim, Norway, [3]Donders Institute for Brain, Cognition and Behaviour, Department Of Cognitive Neuroscience, Nijmegen, Netherlands, [4]University of Regensburg, Department Of Psychiatry And Psychotherapy, Regensburg, Germany, [5]Max Planck Institute for Human Cognitive and Brain Sciences, Department Of Psychology, Leipzig, Germany

The hippocampus is a well-known hub for episodic and spatial processing and memory, as well as more abstract higher-order domains like emotion, language, and theory-of-mind. A common interpretation posits a domain-agnostic coding mechanism that assembles multimodal input into internal representations of places, events, and concepts. However, there is uncertainty around how the involvement of the hippocampus across higher-order thought processes is reflected in its intrinsic organization. For instance, while the anterior and posterior poles of the hippocampus support different behaviours, prior findings have paradoxically indicated a long-axis functional organization that is simultaneously gradual and discrete. Inasmuch as human resting-state fMRI data expressing gradual organization, while other studies suggest that task-based fMRI data should express a more discretized organization. Thus, our aim is to examine long-axis functional topography in task-based 7T fMRI data recorded at sub-millimeter resolution, using a dataset of 22 participants performing a virtual spatial navigation task. We used connectopic mapping, a data-driven analysis for determining topographical features of changes in functional connectivity. Calculating similarity of extrinsic functional connectivity between adjacent voxels yielded maps of connectivity similarity along the hippocampal long axis. These maps were examined for evidence of discrete parcellation, indicated by clusters of voxelwise similarity. Our results indicate a long-axis functional topography that is more modular than gradual. We conclude that task-dependent recruitment of hippocampal computation has a significant effect on the expression of functional topography.

ENTORHINAL GRID-LIKE SIGNALS REFLECT TEMPORAL CONTEXT FOR HUMAN TIMING BEHAVIOR

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Ignacio Polti[1,2], Matthias Nau[2,3], Raphael Kaplan[4], Virginie Van Wassenhove[5], Christian Doeller[1,2]
[1]Max Planck Institute for Human Cognitive and Brain Sciences, Department Of Psychology, Leipzig, Germany, [2]Norwegian University of Science and Technology, Kavli Institute For Systems Neuroscience,, Trondheim, Norway, [3]Max Planck Institute for Human Cognitive and Brain Sciences, Department Of Psychology, Leipzig, United States of America, [4]Universitat Jaume I, Department Of Basic Psychology, Clinical Psychology, And Psychobiology, Castelló de la Plana, Spain, [5]CEA Neurospin, Inserm Cognitive Neuroimaging Unit, Gif sur Yvette, France

The entorhinal cortex (EC) supports the encoding of task regularities. A critical function may be the encoding of temporal context (i.e., forming integrated relational representations of co-occurring events and stimuli). A key neural component in the EC are grid cells, whose activity likely exhibits a six-fold rotational symmetry as a function of gaze direction as measured by functional magnetic resonance imaging (fMRI). Here, we combined fMRI and a time-to-contact estimation task to test whether temporal context modulates this grid-like fMRI activity in the human EC. In addition, we characterized in detail the relationship between trial-wise entorhinal activity and participants' task performance. We found that activity in the EC reflected biases in timing behavior, and that the cross-validated amplitude of grid-like signals indeed depended on the timing errors consistent with temporal-context encoding. These findings suggest that the human EC contributes to adapting internal timing mechanisms to the temporal statistics of the environment in accordance with the predictions from Bayesian models of time perception.

The effect of attention and working memory on the estimation of elapsed time.
Psychological models of time perception involve attention and memory: while attention typically regulates the flow of events, memory maintains timed events or intervals. The precise, and possibly distinct, roles of attention and memory in time perception remain debated. In this behavioral study, we tested 48 participants in a prospective duration estimation task while they fully attended to time or performed a working memory (WM) task. We report that paying attention to time lengthened perceived duration in the range of seconds to minutes, whereas diverting attention away from time shortened perceived duration. The overestimation due to attending to time did not scale with durations. To the contrary, increasing WM load systematically decreased subjective duration and this effect scaled with durations. Herein, we discuss the dissociation between attention and WM in timing and scalar variability from the perspective of Bayesian models of time estimations.

Sequence Memory in the Hippocampal-Entorhinal Region.
Episodic memories are constructed from sequences of events. When recalling such a memory, we not only recall individual events, but we also retrieve information about how the sequence of events unfolded. Here, we focus on the role of the hippocampal-entorhinal region in processing and remembering sequences of events, which are thought to be stored in relational networks. We summarize evidence that temporal relations are a central organizational principle for memories in the hippocampus. Importantly, we incorporate novel insights from recent studies about the role of the adjacent entorhinal cortex in sequence memory. In rodents, the lateral entorhinal subregion carries temporal information during ongoing behavior. The human homologue is recruited during memory recall where its representations reflect the temporal relationships between events encountered in a sequence. We further introduce the idea that the hippocampal-entorhinal region might enable temporal scaling of sequence representations. Flexible changes of sequence progression speed could underlie the traversal of episodic memories and mental simulations at different paces. In conclusion, we describe how the entorhinal cortex and hippocampus contribute to remembering event sequences-a core component of episodic memory.

Event-related potential correlates of stimulus equivalence classes: A study of task order of the equivalence based priming

probes with respect to the stimulus equivalence tests, and among the distinct trial types with each other.
This study investigates the influences of: 1) the task order of two stimulus equivalence classes (SEC) probes, and 2) the possible differences within the equivalence trial types. These factors were analyzed together on both behavioral and event-related potentials (ERP) data. Two groups of normal subjects participated in two successive sessions. In the first session, all participants were trained in the baseline relations among visual stimuli (pseudo-words). In the second session, one group performed the matching-to-sample (MTS) equivalence tests before the equivalence-relatedness-priming (EBRP) task, while the other group performed both tasks in reverse order. In the EBRP task related trial types included trained, symmetrical and equivalence relationships while the unrelated trial types included the same stimuli but without relationships. Event related potentials were recorded separately for related and unrelated conditions during the EBRP task. Results showed that response times to related trials were shorter than those to unrelated ones. At the electrophysiological level, two late waveforms were sensitive to the differences among the stimulus pairs of the EBRP task: Both waveforms were larger for the unrelated than the related conditions. Conversely, there were no main influences of the task order or of the trial types with each other. These results provide evidence that 1) the EBRP task exhibits priming effects among the SEC stimuli, 2) the behavioral and electrophysiological effects were similar regardless of whether the EBRP task was done before or after the MTS tests, and 3) there were no differences within the baseline and derived trial types in the EBRP task.

AUTOBIOGRAPHICAL MEMORY AND REMINISCENCE THERAPY IN HEALTHY OLDER ADULTS : AN FMRI STUDY

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Armelle Viard[1], Andrew Allen[2], Caoilainn Doyle[3], Mikaël Naveau[1], Arun Bokde[4], Hervé Platel[1], Francis Eustache[1], Seán Commins[3], Roche Richard[3]
[1]INSERM-EPHE-UNICAEN UMR_S 1077, Centre Cyceron, Caen, France, [2]Trinity College Dublin, School Of Nursing & Midwifery, Dublin, Ireland, [3]Maynooth University, Dept. Of Psychology, Maynooth, Ireland, [4]Trinity College Dublin, School Of Medicine, Dublin, Ireland

Aims Research has pointed to the benefits of actively engaging one's memory through Reminiscence Therapy (RT). Older adults participated in a RT program over 3 weeks, with functional magnetic resonance imaging (fMRI) before (visit 1) and after (visit 2), to assess the cerebral impact of the intervention. Participants completed an autobiographical memory test (EAMI ; Irish et al., 2008). Methods Eleven older adults (mean age 74,27 +/- 5.14 years old, 4 males) retrieved autobiographical memories (AMs) from cues presented on a screen in the MRI. A flexible factorial design was used (SPM12) with the factors visits 1/2, recent/remote, rehearsed/unrehearsed. A statistical threshold of 0.001 uncorrected, extent threshold k>30 was used. Results The classical AM network (precuneus, medial frontal, lateral temporal gyri, hippocampus) was activated for visits 1 and 2 separately. Direct comparisons showed great activation for visit 2 in left superior medial frontal gyrus, precuneus and anterior hippocampus, compared to visit 1. Remote memories showed greater activation in left precuneus, right inferior frontal and temporal gyri, right posterior hippocampus, compared to recent memories. Unrehearsed memories exhibited greater activation in occipital areas, left middle temporal gyrus and left posterior hippocampus, compared to rehearsed memories. Conclusions There was greater brain activation at visit 2 suggesting a positive effect of RT. Hippocampal activation for remote memories is compatible with the Multiple Trace Theory (Nadel and Moscovitch, 1997). Finally, not rehearsing events engaged a greater occipital and lateral temporal network, suggesting that they were more visual and semantic, compared to repeated events.

SPATIAL MEMORY IN HEALTHY AGEING IS MODULATED BY UPPER-LOWER VISUAL FIELD ASYMMETRIES

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Marion Durteste[1], Louise Van Poucke[1], Sonia Combariza[1], Bilel Benziane[1], Stephen Ramanoël[1,2], Angelo Arleo[1]
[1]Sorbonne Université, INSERM, CNRS, Institut De La Vision, Paris, France, [2]Université Côte d'Azur, Lamhess, Nice, France

AIMS. Visual information is not processed homogeneously across the visual field, as observed in a wide range of behaviours including visual search and object recognition. Despite numerous studies on left-right visual field asymmetry, there is a paucity of data investigating upper-lower visual field differences and their evolution across the lifespan. **METHODS**. To address this gap, twenty-four young (29 ± 4.2 y.o.) and twenty older adults (75 ± 3.7 y.o.) completed a source monitoring task consisting of objects presented in the upper or lower visual field while their gaze was recorded with an eye-tracker. Kinetic and static perimetry was performed on all participants. Analyses were conducted using generalised linear mixed models and multinomial processing tree models. The latter served to estimate the probabilities of recognising an object (item memory) and remembering the position in which it was encoded (spatial memory). **RESULTS**. Data revealed a significant impact of the object's vertical position on spatial memory in older participants. Indeed, the probability of remembering the position of an object that was encountered in the upper visual field was significantly lower in older adults. This age-related difference was not explained by ophthalmological factors (area and light sensitivity of the upper visual field). **CONCLUSIONS**. The vertical position of information influences spatial memory in ageing. The lack of association between participants' visual field characteristics and the observed asymmetry in spatial memory suggests a cognitive basis. This novel finding could yield important environmental design considerations for the older population such as the positioning of informational signage.

DISSOCIABLE ROLES OF SLEEP STAGES IN THE EMERGENCE AND CONSOLIDATION OF TRANSITIVE INFERENCE

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Kareem Abdou[1], Kiriko Choko[1], Mohamed H.Aly[1], Reiko Okubo-Suzuki[1], Shin-Ichi Muramatsu[2], Kaoru Inokuchi[1]
[1]University of Toyama, Department Of Biochemistry, Toyama, Japan, [2]Jichi Medical University, Division Of Neurological Gene Therapy, Tochigi, Japan

Inferential reasoning is a prominent property of higher-order cognition and relies on the systematic organisation of existing knowledge. It has been proposed that sleep facilitates inference, insight and innovative problem-solving. However, it remains unclear how and when the subconscious, but not conscious, brain can create novel ideas. Here, we show that cortical offline, but not online, activity is essential for inference evolution and that activity in rapid-eye movement (REM) sleep-specific brain circuitry is sufficient to inspire inference from inadequate knowledge. In a transitive inference paradigm, mice learned the relationship between five different contexts and could infer novel information that had never been experienced. Mice gained the inference one day, but not shortly, after the complete training. Inhibiting the neuronal computations in the anterior cingulate cortex (ACC) during post-learning sleep, but not during wakefulness, disrupted the inference without affecting the original memories. Furthermore, after insufficient learning, artificial activation of medial entorhinal cortex-ACC dialogue during only REM sleep created inferential knowledge. These findings establish causal evidence for the necessity and sufficiency of REM sleep in reorganising existing knowledge to achieve novel inference, thereby highlighting the power of the idling brain in creativity and cognitive flexibility.

CALCIUM FLUCTUATIONS REPRESENTATIONS OF ENVIRONMENT, NAVIGATION AND EXPLORATION IN MICE PFC

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Melisa Maidana Capitan, Alejandra Alonso, Evelien Schut, Ronny Eichler, Lisa Genzel, Francesco Battaglia
Donders Institute for Brain, Cognition and Behaviour, Radboud University, Neuroinformatics, Nijmegen, Netherlands

Understanding the brain's activity representation during unconstrained behavior comes with the problem of dealing with excessive amounts of degrees of freedom, and the uncertainty of which behavioral feature is being represented. An object in place exploratory task enabled us to reveal multiple levels of environmental representations with co-existing representations of context, position and task performance. The Object Space Task consists of a square arena with objects presented in two corners (similar objects). Different rules, in multiple sessions, provided different levels of variability in the object positions to track memory build up under different conditions. Recurrent behavioural patterns were extracted from mouse trajectories by machine learning techniques and calcium fluorescence activity from mPFC was recorded with a micro-endoscope during task performance. We were able to track individual cells activity during 100 minutes that included exploration, resting and off-recording periods. We found, first, that states space occupation for calcium transients depends on the entire environmental configuration. Clusters emerged corresponding to different combinations of objects positioned in the arena, showing a first level of context encoding. Second, as previously reported with electrophysiological recordings, we showed that animal location can be decoded from calcium traces. Third, the object identity and object locations have separable population calcium transients representations, and this separability is different when there is an object presented at the location. These results show that complex behavioral representations can be extracted from calcium traces in PFC, and that different hierarchies of encoding environment, navigation and exploration can lie within the same representations.

HOMECAGE TESTING DEVICE TO EVALUATE COGNITIVE LEARNING IN A GROUP OF RELATED COMMON MARMOSETS.

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Banty Tia, Cléo Schoeffel, Sabrina Ravel
CNRS-AMU, Institut Des Neurosciences De La Timone Umr 7289, Marseille, France

In the wild, common marmosets generally live in family groups with a breeding pair and their offspring, who will become helpers after their growth. However, this social structure cannot always be preserved in a laboratory environment. One objective of our project is therefore to study the relationship between the social organization of a group and individual performance in a learning task. In this study, the performance of 5 related female marmosets was evaluated. A freely accessible device mounted on the homecage of the animals allowed cognitive tests to be performed without separating individuals from their social group. Each animal was identified by a chip placed on a collar, the detection of which triggered the task with a personalized difficulty level. Three pairs of visual stimuli were presented on a touchscreen in a pseudo-random order. In each pair, the animals had to determine by trial-and-error the rewarded stimulus. Once acquired, the contingency was reversed and the time to acquire the new association was measured. The hierarchical organization of the group was determined based on observations of access to resources (food, resting area, testing device). Daily performance (correct trials, errors, omissions) was measured for each animal. Without food or water restriction, animals performed an average of 271 trials/day ([182-516], N=198 days). We found high heterogeneity in the performance on the task among individuals, demonstrating variability in cognitive flexibility. Ultimately, this approach will allow us to evaluate the influence of group composition on performance in different cognitive tasks.

CORTICAL-HIPPOCAMPAL INFORMATION PROCESSING DURING CLASSICAL CONDITIONING

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Rafael Pedrosa, Federico Stella, Francesco Battaglia
Radboud University, Donders Institute, Nijmegen, Netherlands

A fundamental component for survivance is the ability to employ sensory cues to guide goal-directed behaviors. In this sense, the cortical-hippocampal dialogue plays an important role in the retention of sensorial information and translation of it to a long-term memory. Using auditory trace conditioning (ATC), we studied how the interaction between these two structures are modulated to integrate the auditory information. To answer this question, we combined wide-field voltage imaging from multiple areas in the neocortex with a high-density silicon probe in CA1 in mice. The ATC task was recorded every day for 14 days. In the first half of this period, we trained the animal to discriminate between 2 tones (A and B), with the reward being associated with A. In the other half, we rewired the information, associating the reward now to tone B. Surprisingly, we found a modulation of the Retrosplenial cortex activity in relation with the learning performance. In sync, gamma activity in CA1 also showed a significant increase associated with the performance. Taken together, our findings point out that the Retrosplenial-hippocampal interaction may be fundamental for learning in classical conditioning. We are now studying how networks spanning the entire neocortex participate in encoding the different components of this task.

THE GEOMETRY OF OBJECT REPRESENTATIONS IN CA1 ENSEMBLES DURING SPONTANEOUS EXPLORATION.

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Davide Spalla, Matteo Guardamagna, Federico Stella, Francesco Battaglia
Radboud University, Donders Institute, Nijmegen, Netherlands

Hippocampal neurons are well known to represent multiple features of the animals' position and direction in space. Real-word environments provide a mix of spatial and non-spatial information to the animals, and recent research focused on vector-coding properties of individual hippocampal (and entorhinal) neurons that integrate these two kind of information. However, it is not clear how these properties are distributed across hippocampal ensembles, and how natural exploratory behaviours organizes them. Here, we analyze CA1 ensemble activity in mice while they spontaneously explore arenas populated with objects in stable or changing configurations. Using neural decoding and population analysis techniques, we show that the representation of the different objects at the population level is only partially stable between different exploratory sessions, even when the object configuration is kept fixed. We observe a drop in decoding performance when the decoder is trained and tested in different sessions with the same object configuration. We show that, while the the mean population vector elicited by exploration of different objects changes from session to session, the representation of different objects stays distinct. Furthermore, we show that this instability is not temporally graded, is distributed across the whole population, and does not appear to be actively constrained to keep the representations of different objects orthogonal. Taken together, these results suggest that the informativeness of the neural responses for objects descends from their high-dimensional nature. This discriminability is robust to naturally occurring, population-wide perturbations - with interesting implications for many of the most popular models of hippocampal function.

An experiment often requires precisely timed data acquisition and behavioral monitoring from multiple devices. A problem often encountered by researchers is how to acquire all the different triggers involved with complex behavioral experiments and data acquisition in a synchronized way. Correctly synchronizing all your data is vital for analysis. A setup is rarely all-in-one and ready to record due to the variety of experiments and variables of every research topic. With this problem in mind, we designed a low-cost, open-source teensy-based synchronization system to tackle these challenges. Here we present this synchronization system in combination with a head-fixed virtual reality setup. We were able to demonstrate the flexibility of the setup and synchronization by combining a virtual environment (Unity), running wheel, eye-tracking camera, lick detection, voltage imaging cameras, and open ephys. This system has also been used in combination with 2 photon and Neuropixel recordings. This system is composed of a teensy 4.1 coupled with a web-based python interface and creates a logfile saving 40 analog/digital channels at a rate of 1kHz. This allows for a user-friendly experience with full control of all hardware or triggers used in the setup. In conclusion, we offer here an interactive synchronization system, consisting of a Teensy 4.1, a custom python interface, and software functions that provide a temporally precise, low-cost, and flexible platform, which allows to integrate all the devices necessary for behavioral and neuroscience experiments.

TWO-PHOTON CALCIUM IMAGING CORRELATES OF VISUAL STIMULI IN THE MOUSE RETROSPLENIAL CORTEX DURING HEAD-FIXED VIRTUAL SOCIAL LEARNING

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Arie Kim[1], Francesco Battaglia[2], Jeroen Bos[2], Melisa Maidana Capitan[2], Morgane Audrain[3]
[1]Radboud University, Neuroinformatics, Nijmegen, Netherlands, [2]Radboud University, Donders Institute, Nijmegen, Netherlands, [3]Radboud university, Neuroinformatics, NIJMEGEN, Netherlands

Social animals including both humans and mice navigate through space and scavenge for resources such as food, shelter, or social in-group members. When doing so, the brain gathers sensory inputs and forms a spatial perception. It also links rewarding stimuli with emotions to form salient memories. Many brain regions coordinate for this learning - the thalamus, sensory cortices, striatum, VTA, hippocampus, anterior cingulate cortex, and retrosplenial cortex. Retrosplenial cortex is known to be essential for spatial cognition. However, it is still unclear what specific information retrosplenial cortex and other cortical regions receive, and how their microcircuits process information during social learning. This project aims to study how the neocortical region encodes spatial, social, and emotional information. To address this question, we observed how the retrosplenial neuronal calcium activity responds to spatial and social stimuli given in the form of visual stimuli within a virtual linear environment. We trained mice to run on a treadmill while head-fixed to travel through a virtual environment where different visual fearful and neutral stimuli were presented. Two different stimuli were repeatedly presented in a semi-random order. Calcium fluorescence was recorded using two-photon imaging and the activity of about a hundred cells was stably tracked during the complete experiment. Individual cell's z-scored traces showed consistent patterns across trials for the same stimuli. Our result supports the hypothesis that/suggesting that certain neuronal populations in the retrosplenial cortex respond to certain visual stimuli in a consistent manner.

Opto-vTrap, an optogenetic trap for reversible inhibition of vesicular release, synaptic transmission, and behavior.
Spatiotemporal control of brain activity by optogenetics has emerged as an essential tool to study brain function. For silencing brain activity, optogenetic probes, such as halorhodopsin and archaerhodopsin, inhibit transmitter release indirectly by hyperpolarizing membrane potentials. However, these probes cause an undesirable ionic imbalance and rebound spikes. Moreover, they are not applicable to use in non-excitable glial cells. Here we engineered Opto-vTrap, a light-inducible and reversible inhibition system to temporarily trap the transmitter-containing vesicles from exocytotic release. Light activation of Opto-vTrap caused full vesicle clusterization and complete inhibition of exocytosis within 1 min, which recovered within 30 min after light off. We found a significant reduction in synaptic and gliotransmission upon activation of Opto-vTrap in acute brain slices. Opto-vTrap significantly inhibited hippocampus-dependent memory retrieval with full recovery within an hour. We propose Opto-vTrap as a next-generation optogenetic silencer to control brain activity and behavior with minimal confounding effects.

Observational fear behavior in rodents as a model for empathy.
Empathy enables social mammals to recognize and share emotion with others and is well-documented in non-human primates. During the past few years, systematic observations have showed that a primal form of empathy also exists in rodents, indicating that empathy has an evolutionary continuity. Now, using rodents exhibiting emotional empathy, the molecular and cellular study of empathy in animals has begun in earnest. In this article, we will review recent reports that indicate that rodents can share states of fear with others, and will try to highlight new understandings of the neural circuitry, biochemistry and genetics of empathic fear. We hope that the use of rodent models will enhance understanding of the mechanisms of human empathy and provide insights into how to treat social deficits in neuropsychiatric disorders characterized by empathy impairment.

A Missense Variant at the Nrxn3 Locus Enhances Empathy Fear in the Mouse.
Empathy is crucial for our emotional experience and social interactions, and its abnormalities manifest in various psychiatric disorders. Observational fear is a useful behavioral paradigm for assessing affective empathy in rodents. However, specific genes that regulate observational fear remain unknown. Here we showed that 129S1/SvImJ mice carrying a unique missense variant in neurexin 3 (Nrxn3) exhibited a profound and selective enhancement in observational fear. Using the CRISPR/Cas9 system, the arginine-to-tryptophan (R498W) change in Nrxn3 was confirmed to be the causative variant. Selective deletion of Nrxn3 in somatostatin-expressing (SST+) interneurons in the anterior cingulate cortex (ACC) markedly increased observational fear and impaired inhibitory synaptic transmission from SST+ neurons. Concordantly, optogenetic manipulation revealed that SST+ neurons in the ACC bidirectionally controlled the degree of socially transmitted fear. Together, these results provide insights into the genetic basis of behavioral variability and the neurophysiological mechanism controlling empathy in mammalian brains.

Variability in empathic fear response among 11 inbred strains of mice.
Empathy is an important emotional process that involves the ability to recognize and share emotions with others. We have previously developed an observational fear learning (OFL) behavioral assay to measure empathic fear in mice. In the OFL task, a mouse is conditioned for context-dependent fear when it observes a conspecific demonstrator receiving aversive stimuli. In the present study, by comparing 11 different inbred mouse strains that are commonly used in the laboratory, we found that empathic fear response was highly variable between different strains. Five strains--C57BL/6J, C57BL/6NTac, 129S1/SvImJ, 129S4/SvJae and BTBR T(+) Itpr3(tf) /J--showed observational fear (OF) responses, whereas AKR/J, BALB/cByJ, C3H/HeJ, DBA/2J, FVB/NJ and NOD/ShiLtJ mice exhibited low empathic fear response. Importantly, day 2 OF memory was significantly correlated with contextual memory in the classical fear conditioning among the 11 strains. Innate differences in anxiety, locomotor activity, sociability and preference for social novelty were not significantly correlated with OFL. Interestingly, early adolescent C57BL/6J mice exhibited an increase in acquisition of OF. The level of OFL in C57BL/6J strain was not affected by sex or strains of the demonstrator. Taken together, these data strongly suggest that there are naturally occurring OFL-specific genetic variations modulating empathic fear behaviors in mice. The identification of causal genes may uncover novel genetic pathways and underlying neural mechanisms that modulate empathic fear and, ultimately, provide new targets for therapeutic intervention in human mental disorders associated with impaired empathy.

THE MECHANISMS OF MULTISENSORY INTEGRATION IN THE HIPPOCAMPAL NETWORK

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Karola Kaefer, Morgane Audrain, Jeroen Bos, Francesco Battaglia
Radboud University, Neuroinformatics, Nijmegen, Netherlands

The hippocampus is well established to a main site of spatial coding, but has also been shown to respond to other sensory modalities such as visual and auditory stimuli. We here aim to address the neural mechanisms of sensory integration at the level of the hippocampus and some of its main input and output areas, the perirhinal cortex (PER), lateral entorhinal cortex (LEC) and retrosplenial cortex (RSC). We have here developed a virtual reality task for mice that requires integration of spatial, auditory and visual information ("Multisensory Linear Track"). Briefly, a tone sequence at the beginning of the trial indicated which of the two object sequences positioned along the linear track was rewarded. During this task and sleep, neural activity was recorded with two Neuropixels probes, one targeting the hippocampus and RSC, and the other targeting the PER and LEC. Single unit responses from all four areas were analysed in terms of their selectivity to spatial, auditory and visual input. Units that responded to one or more inputs were further classified into either factorized or conjunctive coding cells, respectively. Between any two brain areas we then searched for functionally coupled cells, and determined whether the response properties of a neuron could be predicted by the responses of upstream neurons it is functionally coupled with. In further analysis we are exploring the mechanisms of population coding in the different areas and inter-area communication.

CORTICAL NETWORKS DIFFERENTIALLY APPROACH CRITICALITY DEPENDING ON FUNCTION AND STATE

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Federico Stella[1], Rafael Pedrosa[1], Francesco Battaglia[2]
[1]Radboud University, Donders Centre, Nijmegen, Netherlands, [2]Radboud University, Donders Institute, Nijmegen, Netherlands

Criticality has been variously hypothesized to provide a fundamental principle for the organization of activity in the brain. By maximizing fluctuations across multiple scales, a network poised at a critical phase transition is thought to support processes which rely on long-range correlations. While extensive experimental and theoretical work speak for the presence of critical (or quasi-critical) dynamics in various portions of the cortex, different notions of criticality are often taken into account, in particular when considering either spatial or temporal scales. Such different definitions might indeed point to distinct phenomena with distinct functional implications. Here we leverage on high-resolution cortical voltage imaging to obtain a comprehensive description of the spatio-temporal organization of activity transients at different levels of resolution. We address this point with the use of various theoretical methods, derived from statistical mechanics and dynamical systems, and by establishing a comparison with branching processes of different types. This collection of analysis shows how multiple signatures of criticality vary along the lines of known cortical functional networks, notably of the Default Mode Network, and unveil the presence of coexisting dynamical states. Furthermore, we show how the degree of both spatial and temporal coherence across the entire cortex, and in particular around the retrosplenial cortex, is highly modulated between wakefulness, REM and NREM sleep, while also being linked with hippocampal activation patterns. Overall our results describe a rich repertoire of cortical dynamical configurations, heterogeneously expressed across networks and states, and point to an association between criticality and memory functions.

BUMBLEBEES CREATE NOVEL ROUTES WITHOUT MENTAL ROTATION, USING VISUAL GUIDANCE

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Joanna Brebner, Joseph Woodgate, Lars Chittka
Queen Mary University of London, School Of Biological And Behavioural Sciences, London, United Kingdom

A cognitive map is thought to allow navigators to mentally represent relevant locations with respect to each other within an external frame of reference. This external frame of reference allows the navigator to mentally rotate space to locate themselves when lost, as well as create new routes. In animals, the creation of novel routes (such as shortcuts) using landscape cues is frequently seen as evidence for the presence of a cognitive map. Opposing this view, several models of animal navigation propose visual-guidance mechanisms such as image-matching which allow for very similar behaviour. We asked if bumblebees (*Bombus terrestris*) could navigate to a rewarding location when their prior experience was restricted to allow them only the use of relative landmark positions, but no path integration or route memories. To do this, we used a three-armed maze, and moved bumblebees between the three chambers using a dark pot. The bees that successfully used unique landmark combinations to reach the rewarding location developed a preference for the correct landmarks during training (prior to the choice test). These same successful individuals were however unable to reach the rewarding location when the task required mental rotation. This is the first experimental evidence that bees are unable to mentally rotate to form new routes. Indeed, the bee behaviour observed was most similar to that predicted through familiarity-based image-matching models, showing no differentiation between landmark orientations at all. These results emphasise the remarkable behavioural flexibility achieved by visual guidance mechanisms in small brains.

A NOVEL TASK TO EXPLORE SENSORY-SPATIAL ASSOCIATION IN FREELY-MOVING MICE

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Olivia Mckissick, Andrea Pierre, Zachary Levin, Keeley Baker, Jason Ritt, Alexander Fleischmann
Brown University, Neuroscience, Providence, United States of America

Behavioral neuroscience presents a growing demand for increasingly naturalistic experiments which better emulate real-world behavior and brain activity. Continual improvement of miniscope technology and behavioral analysis methods has helped to bring the field closer to replicating the natural world while collecting precise neural data. The study of navigation and spatial processing especially benefits from using subjects that are freely moving. I present a novel task designed for miniscope recording during complex sensory-spatial learning and recall in freely moving mice. Mice first navigate to an active cue port at the “North” or “South” end of the arena, where they receive one of two cues. The cue identifies a single rewarded location at either an “East” or “West” port. By requiring mice to navigate to and from different ports we are able to temporally and spatially isolate stimulus identification, navigational planning, and reward. Having two symmetric locations at which otherwise identical cues can be presented allows flexibility to compare allocentric or egocentric spatial rules. The arena is also designed to use different cue modalities: odor, whisker touch, or their combination. Preliminary results show that mice can learn to perform the task when discriminating between aperture widths with their whiskers. Testing with olfactory stimuli and comparison of learning across sensory modalities is ongoing, as is incorporation of miniscope fluorescent imaging of the lateral entorhinal cortex. Together, this work provides a novel sensory-spatial task designed to leverage the benefits of freely-moving behavior while maintaining temporal precision of imaging data and task epochs.

Digging behavior discrimination test to probe burrowing and exploratory digging in male and female mice.
Digging behavior is often used to test motor function and repetitive behaviors in mice. Different digging paradigms have been developed for behaviors related to anxiety and compulsion in mouse lines generated to recapitulate genetic mutations leading to psychiatric and neurological disorders. However, the interpretation of these tests has been confounded by the difficulty of determining the motivation behind digging in mice. Digging is a naturalistic mouse behavior that can be focused toward different goals, that is foraging for food, burrowing for shelter, burying objects, or even for recreation as has been shown for dogs, ferrets, and human children. However, the interpretation of results from current testing protocols assumes the motivation behind the behavior often concluding that increased digging is a repetitive or compulsive behavior. We asked whether providing a choice between different types of digging activities would increase sensitivity to assess digging motivation. Here, we present a test to distinguish between burrowing and exploratory digging in mice. We found that mice prefer burrowing when the option is available. When food restriction was used to promote a switch from burrowing to exploration, males readily switched from burrowing to digging outside, while females did not. In addition, when we tested a model of intellectual disability and autism spectrum disorder that had shown inconsistent results in the marble burying test, the Cc2d1a conditional knockout mouse, we found greatly reduced burrowing only in males. Our findings indicate that digging is a nuanced motivated behavior and suggest that male and female rodents may perform it differently.

Highly efficient neuronal gene knockout in vivo by CRISPR-Cas9 via neonatal intracerebroventricular injection of AAV in mice.
CRISPR-Cas systems have emerged as a powerful tool to generate genetic models for studying normal and diseased central nervous system (CNS). Targeted gene disruption at specific loci has been demonstrated successfully in non-dividing neurons. Despite its simplicity, high specificity and low cost, the efficiency of CRISPR-mediated knockout in vivo can be substantially impacted by many parameters. Here, we used CRISPR-Cas9 to disrupt the neuronal-specific gene, NeuN, and optimized key parameters to achieve effective gene knockout broadly in the CNS in postnatal mice. Three cell lines and two primary neuron cultures were used to validate the disruption of NeuN by single-guide RNAs (sgRNA) harboring distinct

spacers and scaffold sequences. This triage identified an optimal sgRNA design with the highest NeuN disruption in in vitro and in vivo systems. To enhance CRISPR efficiency, AAV-PHP.B, a vector with superior neuronal transduction, was used to deliver this sgRNA in Cas9 mice via neonatal intracerebroventricular (ICV) injection. This approach resulted in 99.4% biallelic indels rate in the transduced cells, leading to greater than 70% reduction of total NeuN proteins in the cortex, hippocampus and spinal cord. This work contributes to the optimization of CRISPR-mediated knockout and will be beneficial for fundamental and preclinical research.

Chronic activation of fear engrams induces extinction-like behavior in ethanol-exposed mice.
Alcohol withdrawal directly impacts the brain's stress and memory systems, which may underlie individual susceptibility to persistent drug and alcohol-seeking behaviors. Numerous studies demonstrate that forced alcohol abstinence, which may lead to withdrawal, can impair fear-related memory processes in rodents such as extinction learning; however, the underlying neural circuits mediating these impairments remain elusive. Here, we tested an optogenetic strategy aimed at mitigating fear extinction retrieval impairments in male c57BL/6 mice following exposure to alcohol (i.e., ethanol) and forced abstinence. In the first experiment, extensive behavioral extinction training in a fear-conditioned context was impaired in ethanol-exposed mice compared to controls. In the second experiment, neuronal ensembles processing a contextual fear memory in the dorsal hippocampus were tagged and optogenetically reactivated repeatedly in a distinct context in ethanol-exposed and control mice. Chronic activation of these cells resulted in a context-specific, extinction-like reduction in fear responses in both control and ethanol-exposed mice. These findings suggest that while ethanol can impair the retrieval an extinction memory, optogenetic manipulation of a fear engram is sufficient to induce an extinction-like reduction in fear responses.

Odor modulates the temporal dynamics of fear memory consolidation.
Systems consolidation (SC) theory proposes that recent, contextually rich memories are stored in the hippocampus (HPC). As these memories become remote, they are believed to rely more heavily on cortical structures within the prefrontal cortex (PFC), where they lose much of their contextual detail and become schematized. Odor is a particularly evocative cue for intense remote memory recall and despite these memories being remote, they are highly contextual. In instances such as posttraumatic stress disorder (PTSD), intense remote memory recall can occur years after trauma, which seemingly contradicts SC. We hypothesized that odor may shift the organization of salient or fearful memories such that when paired with an odor at the time of encoding, they are delayed in the de-contextualization process that occurs across time, and retrieval may still rely on the HPC, where memories are imbued with contextually rich information, even at remote time points. We investigated this by tagging odor- and non-odor-associated fear memories in male c57BL/6 mice and assessed recall and expression in the dorsal CA1 (dCA1) and prelimbic cortex (PL) 1 or 21 d later. In support of SC, our data showed that recent memories were more dCA1-dependent whereas remote memories were more PL-dependent. However, we also found that odor influenced this temporal dynamic, biasing the memory system from the PL to the dCA1 when odor cues were present. Behaviorally, inhibiting the dCA1 with activity-dependent DREADDs had no effect on recall at 1 d and unexpectedly caused an increase in freezing at 21 d. Together, these findings demonstrate that odor can shift the organization of fear memories at the systems level.

Artificially Enhancing and Suppressing Hippocampus-Mediated Memories.
Emerging evidence indicates that distinct hippocampal domains differentially drive cognition and emotion [1, 2]; dorsal regions encode spatial, temporal, and contextual information [3-5], whereas ventral regions regulate stress responses [6], anxiety-related behaviors [7, 8], and emotional states [8-10]. Although previous studies demonstrate that optically manipulating cells in the dorsal hippocampus can drive the behavioral expression of positive and negative memories, it is unknown whether changes in cellular activity in the ventral hippocampus can drive such behaviors [11-14]. Investigating the extent to which distinct hippocampal memories across the longitudinal axis modulate behavior could aid in the understanding of stress-related psychiatric disorders known to affect emotion, memory, and cognition [15]. Here, we asked whether tagging and stimulating cells along the dorsoventral axis of the hippocampus could acutely, chronically, and differentially promote context-specific behaviors. Acute reactivation of both dorsal and ventral hippocampus cells that were previously active during memory formation drove freezing behavior, place avoidance, and place preference. Moreover, chronic stimulation of dorsal or ventral hippocampal fear memories produced a context-specific reduction or enhancement of fear responses, respectively, thus demonstrating bi-directional and context-specific modulation of memories along the longitudinal axis of the hippocampus. Fear memory suppression was associated with a reduction in hippocampal cells active during retrieval, while

fear memory enhancement was associated with an increase in basolateral amygdala activity. Together, our data demonstrate that discrete sets of cells throughout the hippocampus provide key nodes sufficient to bi-directionally reprogram both the neural and behavioral expression of memory.

ABSTRACT SYMBOLIC REPRESENTATION OF SPATIAL LOCATION AND ORDINAL POSITION IN JACKDAWS

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Aylin Apostel[1], Melissa Johnston[2], Kaya Von Eugen[3], Dorian Roeders[1], Jonas Rose[1]
[1]Ruhr University Bochum, Faculty Of Psychology, Neural Basis Of Learning, Bochum, Germany, [2]University of Tuebingen, Institute Of Neurobiology, Animal Physiology, Tuebingen, Germany, [3]Ruhr University Bochum, Faculty Of Psychology, Biopsychology, Bochum, Germany

Remembering a sequence of unique events is a crucial element of cognition. Corvid birds are an excellent animal model for comparative study of such fundamental elements. They show a remarkable range of advanced cognitive abilities that are on par with primates, and their naturally occurring ability to forage and cache food makes them an ideal animal model to study spatial – sequential cognition. For example, some food caching corvid species exhibit episodic-like memory, remembering the location ('where'), time ('when'), and specific type of food ('what') they cached. We probed the ability of two jackdaws to remember the order of visits to three distinct spatial locations. Location cues indicated distinct movement sequences the birds had to cover within a large hexagon-shaped arena. Each cue location was uniquely associated with a specific symbol. The birds had to report their traveled path at a fourth location by selecting the correct symbols in the same order in which they previously visited the locations. Both jackdaws were able to reliably report which sequence they performed. Wireless electrophysiological recordings in the nidopallium caudolaterale (the avian equivalent of mammalian prefrontal cortex) will allow us to examine the neural basis of sequence encoding in an avian brain and allow us to dissociate activity related to specific cue locations, ordinal positions within a sequence, and integrated sequence information. By comparing our results to findings in primates and rodents we will be able to identify general computational principles of sequence representation that are independent of specific brain structures.

INVOLVEMENT OF THE RETROSPLENIAL CORTEX IN SPATIAL MEMORY ACQUISITION AND NAVIGATION

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Urszula Włodkowska, Edyta Balcerek, Bartosz Zglinicki, Rafał Czajkowski
Nencki Institute of Experimental Biology PAS, Laboratory Of Spatial Memory, Warsaw, Poland

Navigation based on formation, storage and retrieval of spatial information is one of fundamental cognitive abilities. We propose a novel version of an automated T-maze task for mice requiring processing of visual information about the external environment. In our design mice are presented with extra maze cues - an LED panel display - through the transparent front wall of the maze. Mice are rewarded with sweet condensed milk administered through custom dispensers constructed out of solenoid valves. The pneumatic actuators moving the doors, the dispensers and the LED panels are all remotely controlled using camera input by software written in the Bonsai environment. We have tested various training protocols - first, utilizing spontaneous alternations in mice, then challenging them to act against spontaneous tendency to alternate. In the last approach the animals were presented with pseudo random sequences of turns, minimizing the risk of developing strategies independent of visual cues. We show that in each of those protocols mice are able to learn to use allothetic cues - both general contexts and salient landmarks, indicating that our modified maze is a useful model for studying navigation and spatial memory. This method reveals the advantage of excluding the influence of human factor and allows for conducting high-throughput experiments. Using this system together with two-photon in vivo IEG imaging I investigated the engagement of the retrosplenial cortex during spatial memory acquisition. My main goal is to find out whether IEG imaging can reveal the existence of engram-like neuronal populations in the RSC.

PROBING NEURAL REPRESENTATIONS OF SCENE PERCEPTION IN A HIPPOCAMPALLY DEPENDENT TASK USING ARTIFICIAL NEURAL NETWORKS

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Markus Frey[1], Christian Doeller[1], Caswell Barry[2]
[1]NTNU, Kavli Institute For Systems Neuroscience, Trondheim, Norway, [2]University College London, Cell & Developmental Biology, London, United Kingdom

Deep artificial neural networks (DNNs) trained through backpropagation provide effective models of the mammalian visual system, accurately capturing the hierarchy of neural responses through primary visual cortex to inferior temporal cortex (IT). However, the ability of these networks to explain representations in higher cortical areas is relatively lacking and considerably less well researched. For example, DNNs have been less successful as a model of the egocentric to allocentric transformation embodied by circuits in retrosplenial and posterior parietal cortex. These brain regions play a central role in spatial memory and perception being part of the 'pipeline' that transforms perceptual information to the spatial representations found in entorhinal cortex and hippocampus. In humans, the Four Mountains task provides a test of egocentric to allocentric topographical processing. We describe a novel virtual environment, inspired by the Four Mountains task, designed to probe the ability of DNNs to transform scenes viewed from different egocentric perspectives. The 'participant' is required to match scenes that correspond to the same configuration of distinct objects viewed from a different perspective, lures consist of the same or similar objects arranged in other configurations. Using a network architecture inspired by the connectivity between temporal lobe structures and the hippocampus, we demonstrate that DNNs trained using a triplet loss can learn this task. Analysis of the representations learnt in these artificial networks revealed late layers accurately encode the allocentric Euclidean distance between objects in the scene, the clearest representation of this quantity being in layers analogous to CA1.

CHARACTERIZATION OF MEMORY RECALL-ASSOCIATED TRANSCRIPTIONAL PROGRAMS IN WILDTYPE AND ANGELMAN SYNDROME MODEL MICE

POSTER SESSION 07 - SECTION: SPACE AND MEMORY

Xiaoning Bi, Wenyue Su, Xiaoning Hao, Michel Baudry
Western University of Health Sciences, Basic Medical Sciences, Comp, Pomona, United States of America

Angelman syndrome (AS) is a rare neurodevelopmental disorder with severe developmental delay, lack of language skills, severe cognitive impairment, motor dysfunction and sleep disorder. Genetic/genomic studies have revealed that *UBE3A* deficiency in neurons is the cause of AS; AS mouse models recapitulate most AS symptoms, including deficits in motor function and learning and memory, anxiety disorders, and altered social interactions. Contextual memory has been widely used to evaluate hippocampus-dependent learning and memory. Several research groups have reported that AS mice show impaired contextual memory recall, although the underlying mechanism remains unsettled. In the present study, we performed RNA-seq on hippocampal samples from both wildtype (WT) and AS mice in control conditions and after fear context recall. Principal component analysis showed that memory recall and genotype were the major drivers of sample variability. There were 281 recall-associated DEGs in WT mice and 268 DEGs in AS mice, when compared to their respective non-recall controls. Of these DEGs, 129 genes were shared between WT and AS mice. KEGG Pathway analyses showed that among the top 10 enriched pathways for DEGs, 5 overlapped between WT and AS mice, while the other 5 were different. Interestingly, the PI3K-AKT pathway was shared by the two genotypes, but the MAPK signaling pathway was only present in AS mice, although both pathways play important roles in synaptic plasticity and memory functions. These results suggest that contextual memory recall in AS mice recruits different transcriptional programs than in WT mice, which could be responsible for recall failure.

STX64, A STEREOID SULFATASE INHIBITOR, IMPROVES COGNITIVE DEFICIENCIES ASSOCIATED TO AGING

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Juan Antonio Fernández Cabrera, Ángel Carrión Rodríguez, Sara Esteban García
Universidad Pablo de Olavide, Physioloy, Anatomy And Cellular Biology, Seville, Spain

Aging produces in brain a progressive oxidative process and neuroinflammation that deteriorates cognition. These brain dysfunctions provoke high economic and social costs to developed societies. For this reason, the search for treatments to prevent cognitive deficits associated with aging is a priority. Previous results suggest that STX64, a steroid sulfatase (STS) inhibitor, improves cognition in neurodegenerative diseases. Here we have designed cellular (immunohistochemistry), molecular (qPCR) and behaviour (mainly, object recognition and passive avoidance for the study of learning and memory) assays to know if subchronic oral treatment with STX64 rescues cognitive dysfunction present in aging mice. Our behavioural results show that STX64 treatment improved cognition in aging mice, reflected as an improvement in object recognition and in passive avoidance tests. At cellular level, aging mice treated with STX64 showed an increase in microglial response and an increase in hippocampal adult neurogenesis. By last, preliminary qPCR assays indicated that hippocampus from aging mice treated with STX64 express lower levels of inflammatory factors mRNA compared with untreated aging mice. Then, our results indicates that STX64 may be a drug with potential therapeutic interest for the treatment of cognitive deficits associated to aging.

Aims: We previously reported no association between prenatal maternal SARS-CoV-2 infection and parent-reported neurodevelopment at 6-months of age. To expand this research, we conducted objective, standardized assessment of neurobehavior to examine the association between prenatal SARS-CoV-2 exposure and neurodevelopment. **Methods:** 137 infants (59 SARS-CoV-2 exposed, 74 unexposed) born at Columbia University affiliated hospitals enrolled in the COVID-19 Mother Baby Outcomes (COMBO) Study and participated in a remote standardized neurodevelopmental assessment between 6-11 months. We administered via Zoom an adapted version of the Developmental Assessment of Young Children, 2nd Edition (DAYC-2). The administration used direct observation, interviewing the caregiver, and parental prompting guided by the examiner. Standard scores on each of the five domains (Cognitive, Gross and Fine Motor, Receptive and Expressive Language) that adjust for age at assessment have a normed mean of 100. **Results:** Analyses of covariance (ANOVAs) revealed no significant group differences on the DAYC-2 domains (*p*'s >0.05) between infants with and without *in-utero* SARS-CoV-2 exposure. After collapsing across the groups, the mean standard scores on the receptive language, expressive language, fine motor, and gross motor domains were 98.0, 97.6, 97.7, and 100.0, respectively. The mean standard score on the cognitive domain was 112.4 **Conclusions:** Consistent with our previous finding showing no association between parent-reported neurodevelopment at 6 months and *in-utero* SARS-CoV-2 exposure, this analysis revealed no significant association between infection exposure and neurodevelopment using DAYC-2 assessment at 6-11 months. Future analysis will include the effects of timing and severity of infection on this objective measure of neurodevelopment.

Elevated prenatal maternal sex hormones, but not placental aromatase, are associated with child neurodevelopment. Fetal exposure to testosterone may contribute to vulnerability for autism spectrum disorder (ASD). It is hypothesized that placental aromatase prevents fetal exposure to maternal testosterone, however, this pathway and the implications for child neurodevelopment have not been fully explored. We examined the relationships between prenatal maternal testosterone and estradiol at 19.2 ± 1.3 weeks, cord blood testosterone and estradiol at birth, placental aromatase mRNA expression, and neurodevelopment using the Social Communication Questionnaire (SCQ), the Behavioral Assessment System for Children, 3rd Edition (BASC-3), and the Empathizing Quotient for Children (EQ-C) at 4.5-6.5 years of age in a sample of 270 Nulliparous-Mothers-to-be (nuMoM2b) study participants. Maternal testosterone levels were positively associated with SCQ scores, but the association was not significant after adjusting for maternal age at delivery, nor was there a significant interaction with sex. Maternal estradiol levels were negatively associated with BASC-3 Clinical Probability scores among males (n = 139). We report a significant interaction effect of cord blood testosterone and fetal sex on both total SCQ scores and t-scores on the Developmental Social Disorders subscale. Placental aromatase was not associated with any neurodevelopmental or hormone measure, but under conditions of low placental aromatase expression, high maternal testosterone was positively associated with SCQ scores in males (n = 46). No other associations between hormone levels

and neurodevelopment were significant. Our findings provide a foundation for further investigation of the mechanisms through which maternal sex hormones and placental steroidogenesis may affect fetal hormone production and neurobehavior.

Behavioral coping phenotypes and associated psychosocial outcomes of pregnant and postpartum women during the COVID-19 pandemic.
The impact of COVID-19-related stress on perinatal women is of heightened public health concern given the established intergenerational impact of maternal stress-exposure on infants and fetuses. There is urgent need to characterize the coping styles associated with adverse psychosocial outcomes in perinatal women during the COVID-19 pandemic to help mitigate the potential for lasting sequelae on both mothers and infants. This study uses a data-driven approach to identify the patterns of behavioral coping strategies that associate with maternal psychosocial distress during the COVID-19 pandemic in a large multicenter sample of pregnant women (N = 2876) and postpartum women (N = 1536). Data was collected from 9 states across the United States from March to October 2020. Women reported behaviors they were engaging in to manage pandemic-related stress, symptoms of depression, anxiety and global psychological distress, as well as changes in energy levels, sleep quality and stress levels. Using latent profile analysis, we identified four behavioral phenotypes of coping strategies. Critically, phenotypes with high levels of passive coping strategies (increased screen time, social media, and intake of comfort foods) were associated with elevated symptoms of depression, anxiety, and global psychological distress, as well as worsening stress and energy levels, relative to other coping phenotypes. In contrast, phenotypes with high levels of active coping strategies (social support, and self-care) were associated with greater resiliency relative to other phenotypes. The identification of these widespread coping phenotypes reveals novel behavioral patterns associated with risk and resiliency to pandemic-related stress in perinatal women. These findings may contribute to early identification of women at risk for poor long-term outcomes and indicate malleable targets for interventions aimed at mitigating lasting sequelae on women and children during the COVID-19 pandemic.

Placental response to maternal SARS-CoV-2 infection.
The coronavirus disease 2019 (COVID-19) pandemic affected people at all ages. Whereas pregnant women seemed to have a worse course of disease than age-matched non-pregnant women, the risk of feto-placental infection is low. Using a cohort of 66 COVID-19-positive women in late pregnancy, we correlated clinical parameters with disease severity, placental histopathology, and the expression of viral entry and Interferon-induced transmembrane (IFITM) antiviral transcripts. All newborns were negative for SARS-CoV-2. None of the demographic parameters or placental histopathological characteristics were associated with disease severity. The fetal-maternal transfer ratio for IgG against the N or S viral proteins was commonly less than one, as recently reported. We found that the expression level of placental ACE2, but not TMPRSS2 or Furin, was higher in women with severe COVID-19. Placental expression of IFITM1 and IFITM3, which have been implicated in antiviral response, was higher in participants with severe disease. We also showed that IFITM3 protein expression, which

localized to early and late endosomes, was enhanced in severe COVID-19. Our data suggest an association between disease severity and placental SARS-CoV-2 processing and antiviral pathways, implying a role for these proteins in placental response to SARS-CoV-2.

Trophoblast inclusions in the human placenta: Identification, characterization, quantification, and interrelations of subtypes.
We sought to examine placentas enriched for trophoblast inclusions (TIs) in order to characterize, quantify, and examine the interrelations between subtypes of TIs to better understand their underlying biology. We examined a cohort of 600 placentas from deliveries between 20 and 43 weeks of gestation. Forty-five percent of the placentas had at least one TI in the two slides examined. Four percent of the placentas had 10 or more TIs and two placentas had more than 70 TIs. Four distinct TI subtypes were observed: inclusionoids (early forming inclusions), inclusions, calcified inclusions, and calcified bodies. We suggest this reflects a developmental trajectory of TI maturation, the timing of which might be useful when comparing TI expression to clinical outcomes.

Perinatal antibiotics alter preterm infant EEG and neurobehavior in the Family Nurture Intervention trial.
Early exposure to antibiotics has been shown to increase risk for poor neurobehavioral development, particularly with regard to attention deficit disorders. Clinically, electroencephalography (EEG) is increasingly used as a biomarker of these deficits. Less is known about the effects of antibiotics on neurobehavioral and neurophysiological outcomes in preterm infants, a population at particularly high risk for attention deficits and perinatal antibiotic exposure. This study examines the effects of perinatal antibiotic exposure on neonatal EEG and attention deficits as measured by the Child Behavior Checklist in 4- to 5-year-old children who were enrolled in an NICU-based randomized controlled trial comparing Family Nurture Intervention (FNI) to standard care. Antibiotic-exposed infants had increased attention problems and there was a main effect of antibiotic exposure such that exposed infants had higher EEG power. This effect was fourfold greater in infants who received standard NICU care compared to those who received the intervention, suggesting a buffering effect of the intervention. We hypothesize that the relationship between antibiotic exposure and altered neurodevelopment may be due to effects of antibiotics on the microbiome, and that FNI may buffer these adverse consequences.

Increased trophoblast inclusions in placentas from prematurely born infants: A potential marker of risk for preterm neurodevelopmental outcomes.
Trophoblast inclusions (TIs) are placental abnormalities of the trophoblast bilayer. Present in 2-8% of full-term placentas, they are associated with poor neurodevelopment, including autism. Although previously unstudied, examination of chorionic villi from 108 preterm births revealed a ~4 fold increase in the frequency of TIs (30.5%). Frequency of TIs was inversely related to gestational age (GA); 43% of placentas <30 weeks and 20% of placentas ≥32 weeks had TIs ($\chi 2 = 4.41$, $p = 0.036$). This increased prevalence in preterm infants suggests that TIs may indicate adverse intrauterine processes or undetected genetic abnormalities and could identify infants at risk for poor neurodevelopment.

Family Nurture Intervention in the Neonatal Intensive Care Unit improves social-relatedness, attention, and neurodevelopment of preterm infants at 18 months in a randomized controlled trial.
Preterm infants are at high risk for adverse neurodevelopmental and behavioral outcomes. Family Nurture Intervention (FNI) in the Neonatal Intensive Care Unit (NICU) is designed to counteract adverse effects of separation of mothers and their preterm infants. Here, we evaluate effects of FNI on neurobehavioral outcomes.

EFFECTS OF SUSTAINED COGNITIVE ACTIVITY ON EXECUTIVE FUNCTIONS IN HEALTHY AGED ADULTS : TOWARD A GAIN OF 10 YEARS OF COGNITIVE EFFICIENCY

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Jocelyne Plumet[1], David Clarys[2]
[1]Centre de Recherches sur la Cognition et l'Apprentissage, Umr Cnrs 7295 Cerca, Poitiers Cedex , France, [2]Centre de Recherches sur la Cognition et l'Apprentissage, Umr Cnrs 7295 Cerca, Poitiers Cedex, France

Aims. Neural plasticity associated with environmental stimulations may counter age-related declines in brain functions. This research examines whether continued cognitive activation is a critical factor in maintaining executive abilities and whether educational level and aging may interact. **Methods.** Executive functions were explored in 178 healthy participants aged 69-88 years, 73 voluntary applicants in a multi-domain cognitive program for 15 years and 105 controls. They were divided in 8 groups defined by their age and their educational level. Inhibition and cognitive flexibility were assessed using the Stroop test, the modified card sorting test, the trail making test and an alternated verbal fluency test. **Results.** Variance analyses in control groups revealed significant main effects of aging and educational level in inhibition and cognitive flexibility tasks. The overall effects remained significant after the inclusion of the stimulated groups into the analyses, but the continuous stimulation resulted in a significant beneficial effect in all executive tasks. Surprisingly, this outcome mostly occurred at similar rates regardless of age and educational attainment (no interaction). Moreover, stimulated group's executive performance matched those of 10 years younger control counterparts. **Conclusions**. These findings suggest that cognitive exercise leads to consistent and significant gains or delays the decline of executive functions. The facilitation in processing efficiency appears transferable since the tasks in the cognitive program do not bear similarities with those in the study. Further studies will be required to determine whether maintenance of cognitive activation provides greater compensatory resources and/or contributes to the maintenance of cognitive and cerebral integrity.

Background: Growing research has focused on plasma phospho-tau 181 (p-tau181), amyloid-beta (Aβ42/40), neurofilament-light (NfL), and glial fibrillary acidic protein (GFAP) as blood biomarkers for Alzheimer's disease. However, their predictive validity for age-related cognitive decline without dementia remains unclear. Further, it is unknown whether p-tau181 is present in brain tissue and synapses of aged controls without dementia. Aims: Here, we tested whether plasma p-tau181, Aβ42/40, NfL, and GFAP predict longitudinal cognitive decline in cognitively unimpaired late-adulthood participants. In a separate neuropathological study, we examined whether there were differences in levels of p-tau181 in total homogenate and synaptoneurosome preparations between aged controls, Alzheimer's cases, and mid-life controls. Methods: General cognitive ability and plasma p-tau181, Aβ40, Aβ42, NfL, and GFAP concentration were measured in 195 participants at ages 72 and 82. Levels of p-tau181 in total homogenate and synaptic fractions were compared with western blot (n = 10-12 per group). Results: Elevated baseline plasma p-tau181, NfL, and GFAP predicted steeper general cognitive decline. Further, increasing p-tau181 over time predicted steeper general cognitive decline. We found no significant differences in p-tau181 in total homogenate or synaptoneurosome preparations between aged controls, Alzheimer's disease cases, and young controls. Conclusions: Baseline plasma p-tau181, NfL, and GFAP, as well as subsequent change in plasma p-tau181 may represent rare biomarkers of differences in cognitive ageing across the 8th decade of life and may play a role in synaptic function in the brain.

LONGITUDINAL COGNITIVE DECLINE AND BLOOD-BRAIN BARRIER PERMEABILITY IN A POPULATION COHORT

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Aftab Bakhtiari[1,2,3], Mark Vestergaard[3], Krisztina Benedek[2], Birgitte Fagerlund[4], Henrik Larsson[3], Martin Lauritzen[1,2], Ulrich Lindberg[3]
[1]University of Copenhagen, Center For Healthy Aging And Department Of Neuroscience, Copenhagen, Denmark, [2]The Neuroscience Centre, Rigshospitalet Glostrup, University of Copenhagen, Department Of Clinical Neurophysiology, Glostrup, Denmark, [3]Copenhagen University Hospital Rigshospitalet, Functional Imaging Unit, Department Of Clinical Physiology, Nuclear Medicine, And Pet, Glostrup, Denmark, [4]University of Copenhagen, Department Of Psychology, Copenhagen, Denmark

Aims: Aging is associated with a decline in several cognitive domains. Furthermore, there is a significant interest in finding biomarkers to predict healthy aging from pathological decline. We have examined the trajectory of cognitive aging by studying a population cohort in a longitudinal design spanning ten years and investigated the potential of blood-brain barrier permeability (BBB) as a biomarker for cognitive decline. Methods: 207 participants from the Metropolit Birth Cohort completed a neuropsychological test battery assessing episodic memory, working memory, processing speed, attention, and verbal functions at three different time points. BBB was assessed by dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) by injection of a gadolinium-based contrast agent. Permeability was calculated using tracer kinetic modeling ($p>0.339$). Results: Participants had a time-dependent decrease in episodic memory, processing speed, attention, and working memory (Table 1). Verbal functions were somewhat stable, with a slight increase with time. The number of school years was a positive mediator for processing speed, working memory, and verbal functions. Conversely, increased episodic memory score was associated with fewer school years. There were no significant associations between BBB permeability in the hippocampus or white matter and cognition. Conclusion: Longitudinal studies assessing the same individuals across time are essential to understand cognitive changes occurring in healthy aging. The present results find support for a time-dependent decline in several cognitive modalities. School years seem to be a positive mediator in maintaining processing speed, working memory, and verbal

functions.

CHRONIC INFLAMMATION IMPACTS WHITE MATTER IN BOTH NEURODEVELOPMENT AND COGNITIVE AGEING: A MULTI-OMICS APPROACH

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Eleanor Conole[1], Simon Cox[2], Riccardo Marioni[3], James Boardman[4]
[1]University of Edinburgh, Lothian Birth Cohort Studies,department Of Psychology, Edinburgh, United Kingdom, [2]The University of Edinburgh, Lothian Birth Cohort Studies, Department Of Psychology, Edinburgh, United Kingdom, [3]University of Edinburgh, Centre For Genomic And Experimental Medicine, Edinburgh, United Kingdom, [4]University of Edinburgh, Medical Research Council Centre For Reproductive Health, Edinburgh, United Kingdom

Aims: To investigate the impact of chronic inflammation on brain ageing across the lifecourse. **Methods:** A DNA methylation (DNAm) signature of C-Reactive Protein (CRP) was trained out-of-sample by creation of a weighted score from relevant CpG sites; these DNAm scores were then projected across both infant and adult cohorts to examine the consequences of inflammation on brain health outcomes at different life stages. In the infant brain cohort (Theirworld Edinburgh Birth Cohort), 214 infants had neuroimaging (MRI, DTI) and DNAm (Illumina EPIC array) data available; of these, 127 were classified as preterm (< 37 weeks gestational age at birth). In the older age cohort (Lothian Birth Cohort), 521 cognitively normal adults (age ~ 73 years) had relevant data available. In both cohorts, linear models were used to examine inflammation–brain health associations. **Results:** In the infant cohort, preterm infants had higher DNAm CRP scores than term infants; infants who sustained multiple clinical inflammatory hits (e.g. preeclampsia, sepsis) also had higher DNAm CRP scores. Overall, DNAm CRP showed significant associations with brain white matter both globally and regionally in preterm infants. In the older-age cohort, DNAm CRP was also associated with white matter globally and regionally. White matter mediated the relationship between DNAm CRP and cognition, demonstrating a link between inflammation and cognitive ageing. **Conclusions:** This work supports the hypothesis that inflammation has adverse outcomes for brain white matter and highlights the use-case for using DNAm profiles to infer baseline inflammatory status in population cohorts.

Structural brain correlates of serum and epigenetic markers of inflammation in major depressive disorder.
Inflammatory processes are implicated in the aetiology of Major Depressive Disorder (MDD); however, the relationship between peripheral inflammation, brain structure and depression remains unclear, partly due to complexities around the use of acute/phasic inflammatory biomarkers. Here, we report the first large-scale study of both serological and methylomic signatures of CRP (considered to represent acute and chronic measures of inflammation respectively) and their associations with depression status/symptoms, and structural neuroimaging phenotypes (T1 and diffusion MRI) in a large community-based sample (Generation Scotland; N = 271, N = 609). Serum CRP was associated with overall MDD severity, and

specifically with current somatic symptoms- general interest (β = 0.145, P = 6 × 10) and energy levels (β = 0.101, P = 0.027), along with reduced entorhinal cortex thickness (β = -0.095, P = 0.037). DNAm CRP was significantly associated with reduced global grey matter/cortical volume and widespread reductions in integrity of 16/24 white matter tracts (with greatest regional effects in the external and internal capsules, β= -0.12 to -0.14). In general, the methylation-based measures showed stronger associations with imaging metrics than serum-based CRP measures (βaverage = -0.15 versus βaverage = 0.01 respectively). These findings provide evidence for central effects of peripheral inflammation from both serological and epigenetic markers of inflammation, including in brain regions previously implicated in depression. This suggests that these imaging measures may be involved in the relationship between peripheral inflammation and somatic/depressive symptoms. Notably, greater effects on brain morphology were seen for methylation-based rather than serum-based measures of inflammation, indicating the importance of such measures for future studies.

HEMISPHERIC VERSUS WHOLE-BRAIN IRRADIATION INDUCED NEUROTOXICITY: LONGITUDINAL STUDIES IN THE RAT

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Fatima-Azzahra Dwiri, Julie Becam, Carole Brunaud, Laurent Chazalviel, Samuel Valable, Myriam Bernaudin, Elodie A Peres, Omar Touzani
Normandie Univ, UNICAEN, CNRS, ISTCT, Gip Cyceron, Caen, France

Aims: Although radiotherapy improves patient prognosis suffering brain cancer, it also affects healthy brain and induces irreversible cognitive deficits in long-surviving patients. Quality of life of patients has taken greater importance in neuro-oncology and current clinical paradigm is to specifically target brain tumors while sparing surrounding healthy tissue. Thereby, new irradiation modalities have been developed, but scientific evidence is strongly needed to demonstrate their value in reducing radiation toxicities. Thus, this study aims to characterize the effects of hemispheric-brain irradiation on tissue integrity and cognition compared to whole-brain irradiation. **Methods**: Wistar rats were divided into control (CTL), whole-brain (WBI) and hemispheric-irradiated (HBI) groups. Fractionated irradiation (30Gy) was applied using a preclinical irradiator (X-RAD-225Cx). General condition, brain MRI and behavioral tests were performed longitudinally up to six-months to assess brain tissue injury, short-term (novel object recognition) and long-term (passive avoidance) memories. **Results**: HBI did not induce weight loss and mortality as compared to WBI. Similarly, in comparison to WBI, more restricted irradiation did not induce significant memory deficits as quantified by passive avoidance and novel recognition object tests. MRI did not show any radio-necrosis nor edema in rats submitted either to WBI or HBI at all the time points analyzed. Nonetheless, brain and hemispheric atrophies were revealed at six-months respectively. Vascular and diffusion MRI revealed major alterations in brain tissue in WBI rats but not in those with HBI. **Conclusions**: These results show that restricted brain irradiation preserves indeed brain tissue and induces less cognitive deficits as compared to whole-brain irradiation.

ASSESSMENT OF MOTOR PERFORMANCE AND NIGROSTRIATAL DOPAMINERGIC SYSTEM IN L66 MICE WITH FRONTOTEMPORAL DEGENERATION-LIKE TAUOPATHY

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Maciej Zadrożny[1], Patrycja Drapich[1], Sandra Mirończuk[1], Anna Gąsiorowska[1], Grażyna Niewiadomska[2], Wiktor Niewiadomski[1]
[1]Mossakowski Medical Research Institute Polish Academy of Sciences, Department Of Applied Physiology, Warsaw, Poland, Poland, [2]Nencki Institute of Experimental Biology PAS, Laboratory Of Preclinical Testing Of Higher Standard, Warsaw, Poland

Aim: The aim of the study was to evaluate the motor functions and dopaminergic system status in young and aged L66 heterozygous and homozygous mice, serving as a transgenic model of frontotemporal dementia. **Methods:** L66 homozygous (L66Homo) and L66 heterozygous (L66Het) transgenic mice expressing full-length human tau carrying P301S and G335D mutations and the NMRI wild type mice at 5 and 10 months of age was used. To test motor learning and function accelerated and fixed variants of RotaRod test were applied. The accelerated RotaRod test took 4 days with the rod acceleration from 1 to 45 rpm over the 5 min trial. One-day fixed RotaRod test consisted of 4 trials in each rotation speed 5, 10, 15, 20, 25 rpm over 1 min. Results were expressed as time spent on the rotating rod. Pearson's Correlation coefficient between individual results on consecutive days was calculated. Immunohistochemical staining against tyrosine hydroxylase was used to evaluate the dopaminergic system. **Results:** 5 month old animals from all lines did not show motor deficits in both tests. The most prominent decline in motor abilities was observed in 10 month old L66 homozygotes.10 month old L66 heterozygotes were not impaired with respect to NMRI in both tests. Correlation analysis revealed that there was a distinct worsening of motor performance with age in most of L66 Homo mice, however in small subset motor performance remains unimpaired. **Conclusion:** Both rotarod test showed clear motor impairment in ageing L66Homo mice which appears to be associated with dopaminergic impairment.

The gut microbiota is known to influence behavior and cognitive function in mice, while host physiology has been shown to influence microbial activity vice versa. However, the underlying mechanisms governing this cross-talk are still incompletely understood. Our study aims to investigate the metabolic basis of this interconnection in relation to spatial memory function and its decline manifesting during normal aging. To this end, we collected fecal metabolomics, metagenomics and transcriptomics data (hippocampus, colon, liver) from mice of different age groups along with measures of spatial memory performances obtained through the Barnes maze test. To evaluate spatial memory function, we calculated the average learning pace (velocity of improvement across multiple Barnes maze tests) for each mouse. To assess the metabolic functionality of mice gut microbiota, we obtained Metagenomic Assembled Genomes (MAGs) from metagenomic data and used this data to reconstruct high-quality metabolic models of the bacterial species. In a later step, we will build an integrated metabolic metamodel of the host and its microbiome by joining the microbial metabolic networks with a mouse metabolic model derived from the human analogue Recon3D. Associations between host as well as microbiota metabolic functions and spatial memory performances will be identified through classical statistic and machine learning approaches. The metamodel will be used to study the links between cognition-associated host and bacterial metabolic functions in order to highlight potential routes of interaction between bacterial and brain metabolism. Preliminary results from metabolomics data indicate an important role of microbially-produced nucleotides in modulating spatial memory performance.

SUCCESSFUL COGNITIVE AGING RELIES ON HEALTHY ADULT BORN DENTATE NEURONS

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Nicolas Blin[1], Loreen Rupprecht[2], Lie Chichung[3], Fanny Farrugia[1], Vanessa Charrier[1], Djoher Nora Abrous[2]
[1]Univ. Bordeaux, Inserm, Neurocentre Magendie U1215, Bordeaux, France, [2]Univ. Bordeaux, INSERM, Neurocentre Magendie U1215, Bordeaux, France, [3]Emil Fischer Center, Institute Of Biochemistry, Erlangen, Germany

The progressive decline of memory associated with aging is variable between individuals; some retain good memory performances while others suffer substantial loss of memory abilities. Adult neurogenesis in the dentate gyrus plays an essential role in learning and memory and represents a good candidate for the resilience/vulnerability to cognitive aging as animals with preserved memory abilities show higher levels of neurogenesis at old age. In this project, we aim to determine the role of adult dentate granule neurons (adu-DGNs) born throughout adult life in the development of memory deficits with age. First, we showed using the immediate early gene Zif268 as a proxy for neuronal activity that adu-DGNs are less responsive to the learning task in old aged impaired rats (Vulnerable) compared to the aged rats with preserved memory (Resilient). Next, we aimed to understand the mechanisms involved in such differences in responsiveness of adu-DGNs. We investigated possible alterations in their morphology and/or cellular homeostasis when animals were middle-age, to detect early signs of dysfunction that could lead to memory loss. To do so, the dendritic complexity, mitochondrial network and cellular senescence were investigated. We showed that adu-DGNs display similar morphological characteristics between populations and no sign of cellular senescence. However, we observed in the vulnerable population an impairment of their mitochondrial network in a specific sub-dendritic compartment. Memory deficits observable at old age are linked to a decrease of adu-DGNs reactivity in response to learning that could be related to an early alteration of their metabolism starting at middle-age.

EARLY-ONSET AND LATE-ONSET CALORIE RESTRICTION DIFFERENTLY MODULATE ANXIETY-LIKE BEHAVIOR IN AGING FEMALE WISTAR RATS

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Milica Prvulovic, Smilja Todorovic, Desanka Milanovic, Andjela Vukojevic, Valentina Simeunovic, Milena Jovic, Aleksandra Mladenovic
Institute for Biological Research „Siniša Stanković“- National Institute of Republic of Serbia University of Belgrade, Department Of Neurobiology, Belgrade, Serbia

Aims: Calorie restriction (CR) is known to prolong lifespan and healthspan, - life period free of age-related diseases. However, generality of CR’s beneficial effect is being questioned recently. Few studies showed that the outcome of CR could vary depending on its onset and duration. Herein, we examined and compared potential of different CR paradigms to modulate anxiety-like behavior. Methods: Ad libitum (AL) fed animals were used as controls. Female Wistar rats of different age (adult, middle-aged and aged) were exposed to CR (60% of AL), to examine the effect of early-onset CR (EOCR) and late-onset CR (LOCR). Open field (OF) and Light-dark box (LDB) test were used for anxiety assessment. Results: Aged LOCR animals had decreased number of entries and time spent in the central area of the OF. LDB test results, however, implied a protective effect of EOCR since both middle-aged and aged EOCR animals showed increased number of entries in the light compartment and spent more time in the door area or in the light compartment. LOCR had different effect depending on animals’ age at the CR onset. Conclusions: EOCR ameliorates anxiety-like behavior and this effect seems to persevere till old age. Implementing CR later in life should be taken with caution, since its’ effect could vary from protective to detrimental, depending on the onset. Additionally, different results were obtained using OF and LDB, suggesting that more than one test should be used to provide proper insight in certain behavioral changes.

Late-Onset Calorie Restriction Worsens Cognitive Performances and Increases Frailty Level in Female Wistar Rats.
The current study aims to determine the potential benefits of calorie restriction (CR), one of the most promising paradigms for life span and healthspan extension, on cognitive performances in female Wistar rats during aging. As a measure of a healthspan, we evaluated the effects of different onset and duration of CR on frailty level. Female Wistar rats were exposed to either ad libitum (AL) or CR (60% of AL daily intake) food intake during aging. Two different CR protocols were used, life-long CR with an early-onset that started at the adult stage (6 months) and 3-month-long CR, started at the middle (15 months) and late-middle (21 months) age, thus defined as a late-onset CR. The effects of CR were evaluated using open-field, Y-maze, and novel object recognition tests. We broadened 2 tools for frailty assessment currently in use for experimental animals, and in alignment with our previous study, we created a physical-cognitive frailty tool that combines both physical and cognitive performances. Our results clearly showed that CR effects are highly dependent on CR duration and onset. While a life-long restriction with an early-onset has been proven as protective and beneficial, short-term restriction introduced at late age significantly worsens an animal's behavior and frailty. These results complement our previous study conducted in males and contribute to the understanding of sex differences in a response to CR during aging.

Pharmacological intervention in a transgenic mouse model improves Alzheimer's-associated pathological phenotype: Involvement of proteasome activation.
Alzheimer's disease (AD) is the most common form of dementia worldwide, characterized by a progressive decline in a variety of cognitive and non-cognitive functions. The amyloid beta protein cascade hypothesis places the formation of amyloid beta protein aggregates on the first position in the complex pathological cascade leading to neurodegeneration, and therefore AD might be considered to be a protein-misfolding disease. The Ubiquitin Proteasome System (UPS), being the primary protein degradation mechanism with a fundamental role in the maintenance of proteostasis, has been identified as a putative therapeutic target to delay and/or to decelerate the progression of neurodegenerative disorders that are characterized by

accumulated/aggregated proteins. The purpose of this study was to test if the activation of proteasome in vivo can alleviate AD pathology. Specifically by using two compounds with complementary modes of proteasome activation and documented antioxidant and redox regulating properties in the 5xFAD transgenic mice model of AD, we ameliorated a number of AD related deficits. Shortly after proteasome activation we detected significantly reduced amyloid-beta load correlated with improved motor functions, reduced anxiety and frailty level. Essentially, to our knowledge this is the first report to demonstrate a dual activation of the proteasome and its downstream effects. In conclusion, these findings open up new directions for future therapeutic potential of proteasome-mediated proteolysis enhancement.

Aging is defined as a biological process time-related that is associated with structural and physiological alterations in the hippocampus, specifically with brain mechanisms known as neuroinflammation and neuronal loss. In this context, one of the most common procedures to delay age-related cognitive decline is the caloric restriction (CR) diet. Hippocampal samples from three different groups of male Wistar rats; old rats fed on a CR diet from 4 months of age, old rats with unrestricted access to food (*Ad Libitum, AL*) and young rats, were analysed by immunohistochemical and neurogenesis markers. By means of immunohistofluorescence we assessed the distribution of NeuN, expressed by neurons, and of Iba-1, expressed by microglial cells; to evaluate the neuronal loss and neuroinflammation, respectively. To evaluate neurogenesis, staining for doublecortin (DCX), an immature neuron marker, was performed. Our results showed that CR had a positive effect in slowing-down structural and functional hippocampal aged-related changes as CR rats showed a significant increase in neuronal density and a decrease in neuroinflammation compared with AL rats. Moreover, CR slightly enhanced short-term hippocampal-dependent memory, as assessed with the Y-maze object recognition task. However, CR diet did not prevent against age-related decline in neuronal production. Altogether, these results support a positive effect of CR on age-dependent hippocampal dysfunctions.

CONDITIONAL DELETION OF CB1 RECEPTOR IN THE HIPPOCAMPUS ACCELERATES AGEING SIGNS IN MATURE MICE

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Michela Palmisano, Andreas Zimmer, Andras Bilkei-Gorzo
University of Bonn, Medical Faculty, Institute Of Molecular Psychiatry, Bonn, Germany

Aims: Ageing is characterized by a series of cellular and molecular alterations in the brain, most significantly in the hippocampus. During ageing endocannabinoid system activity declines, including the function of cannabinoid type-1 (CB1) receptors. Previous studies have shown that decreased cannabinoid system signaling, due to constitutive genetic deletion of the CB1 receptor in mice, leads to an early onset of ageing signs in the brain like learning deficits and hyperactivation of glial cells. In the present study, we asked whether the CB1 receptor exerts its protective effect locally or it has a systemic action. To answer this question, we tested the learning ability, histological and expression changes in the hippocampus of mice with hippocampus-specific deletion of the CB1 receptor. Methods: Recombinant adeno-associated viruses expressing Cre recombinase or the Venus reporter gene were stereotaxically injected into the hippocampus of 2-month-old $CB1_{floxed/floxed}$ mice. Four months later, we assessed the social recognition memory of the 6-month-old mice in the partner recognition test. Finally, microglia and astrocyte density and morphology, expression of the CB1 receptor and proinflammatory cytokines were measured. Results: Efficacy of CB1 deletion was proved by showing reduced CB1 protein and mRNA levels in the hippocampus of Cre injected mice. We found that Cre injected mice were unable to discriminate the previously seen partner compared to the age-matched controls and the hippocampal expression of the proinflammatory cytokine TNF-alpha was significantly upregulated. Conclusions: Our results suggest that local CB1 receptor activity is required to prevent cognitive and cellular age-related changes.

Efficacy of Δ -Tetrahydrocannabinol (THC) Alone or in Combination With a 1:1 Ratio of Cannabidiol (CBD) in Reversing the Spatial Learning Deficits in Old Mice.
Decline in cognitive performance, an aspect of the normal aging process, is influenced by the endocannabinoid system (ECS). Cannabinoid receptor 1 (CB1) signaling diminishes with advancing age in specific brain regions that regulate learning and memory and abolishing CB1 receptor signaling accelerates cognitive aging in mice. We recently demonstrated that prolonged exposure to low dose (3 mg/kg/day) Δ-tetrahydrocannabinol (THC) improved the cognitive performances in old mice on par with young untreated mice. Here we investigated the potential influence of cannabidiol (CBD) on this THC effect, because preclinical and clinical studies indicate that the combination of THC and CBD often exhibits an enhanced therapeutic effect compared to THC alone. We first tested the effectiveness of a lower dose (1 mg/kg/day) THC, and then the efficacy of the combination of THC and CBD in 1:1 ratio, same as in the clinically approved medicine Sativex. Our findings reveal that a 1 mg/kg/day THC dose still effectively improved spatial learning in aged mice. However, a 1:1 combination of THC and CBD failed to do so. The presence of CBD induced temporal changes in THC metabolism ensuing in a transient elevation of blood THC levels. However, as CBD metabolizes, the inhibitory effect on THC metabolism was alleviated, causing a rapid clearance of THC. Thus, the beneficial effects of THC seemed to wane off more swiftly in the presence of CBD, due to these metabolic effects. The findings indicate that THC-treatment alone is more efficient to improve spatial learning in aged mice than the 1:1 combination of THC and CBD.

Depletion of TrkB Receptors From Adult Serotonergic Neurons Increases Brain Serotonin Levels, Enhances Energy Metabolism and Impairs Learning and Memory.
Neurotrophin brain-derived neurotrophic factor (BDNF) and neurotransmitter serotonin (5-HT) regulate each other and have been implicated in several neuronal mechanisms, including neuroplasticity. We have investigated the effects of BDNF on serotonergic neurons by deleting BDNF receptor TrkB from serotonergic neurons in the adult brain. The transgenic mice show increased 5-HT and Tph2 levels with abnormal behavioral phenotype. In spite of increased food intake, the transgenic

mice are significantly leaner than their wildtype littermates, which may be due to increased metabolic activity. Consistent with increased 5-HT, the proliferation of hippocampal progenitors is significantly increased, however, long-term survival of newborn cells is unchanged. Our data indicates that BDNF-TrkB signaling regulates the functional phenotype of 5-HT neurons with long-term behavioral consequences.

AGE-RELATED NEURONAL LOSS IN THE LOCUS COERULEUS IS INFLUENCED BY CANNABINOID RECEPTOR TYPE-1 ACTIVITY AND RESPONSIBLE FOR ATTENTION DEFICITS

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Alessandra Gargano[1], Eva Beins[2], Andreas Zimmer[1], Andras Bilkei-Gorzo[1]
[1]University of Bonn, Institute Of Molecular Psychiatry, Bonn, Germany, [2]University of Bonn, Institute Of Human Genetics, Bonn, Germany

Introduction: Our laboratory has previously shown that CB1r activity is neuroprotective and a modulator of brain ageing. In this study, we investigate how the endocannabinoid system affects noradrenergic neurons in the Locus Coeruleus (LC), which are vulnerable to age-related changes. **Methods:** The number of LC neurons was determined using stereological counting in wild-type animals to confirm an aging effect and to establish a timeline of LC age-related neurodegeneration. Next, we compared wild-type and CB1r knockout ($Cnr1^{-/-}$) mice. Markers for noradrenergic innervation, inflammation, and DAGLα protein expression have been analyzed by immunohistochemistry. To test whether the loss of LC noradrenergic neurons is responsible for age-related deficits in fear memory and attention, we treated young mice with DSP-4 toxin, reducing LC neuronal numbers to the level typical of old animals. Then, we compared their performance with old mice in the Fear Conditioning and 5CSRTT behavioral tests. **Results:** Our data show that in wild-type mice there is an age-related neuronal loss in LC starting in middle aged animals. $Cnr1^{-/-}$ mice show less noradrenergic neurons and noradrenergic terminals compared to age-matched wild-type controls. Attention was decreased both in old mice and in DSP-4 treated young animals. Fear memory was influenced by the age but not by the deletion of noradrenergic neurons. **Conclusions:** All together our data suggest that CB1r activity is protective for noradrenergic neurons during ageing and that a reduction in the number of noradrenergic neurons could be responsible for attention deficits in ageing but not for the altered fear learning and memory.

Lack of Cannabinoid Receptor Type-1 Leads to Enhanced Age-Related Neuronal Loss in the Locus Coeruleus.
Our laboratory and others have previously shown that cannabinoid receptor type-1 (CB1r) activity is neuroprotective and a modulator of brain ageing; a genetic disruption of CB1r signaling accelerates brain ageing, whereas the pharmacological stimulation of CB1r activity had the opposite effect. In this study, we have investigated if the lack of CB1r affects noradrenergic neurons in the locus coeruleus (LC), which are vulnerable to age-related changes; their numbers are reduced in patients with neurodegenerative diseases and probably also in healthy aged individuals. Thus, we compared LC neuronal numbers between cannabinoid 1 receptor knockout () mice and their wild-type littermates. Our results reveal that old mice have less noradrenergic neurons compared to their age-matched wild-type controls. This result was also confirmed by the analysis of the density of noradrenergic terminals which proved that mice had less compared to the wild-type controls. Additionally, we assessed pro-inflammatory glial activity in the LC. Although the density of microglia in mice was enhanced, they did not show enhanced inflammatory profile. We hypothesize that CB1r activity is necessary for the protection of noradrenergic neurons, but its anti-inflammatory effect probably only plays a minor role in it.

Nerve growth factor-mediated photoablation of nociceptors reduces pain behavior in mice.
Nerve growth factor (NGF) and its receptors TrkA and p75 play a key role in the development and function of peripheral nociceptive neurons. Here, we describe novel technology to selectively photoablate TrkA-positive nociceptors through delivery of a phototoxic agent coupled to an engineered NGF ligand and subsequent near-infrared illumination. We demonstrate that this approach allows for on demand and localized reversal of pain behaviors in mouse models of acute, inflammatory, neuropathic, and joint pain. To target peripheral nociceptors, we generated a SNAP-tagged NGF derivative NGF that binds to TrkA/p75 receptors but does not provoke signaling in TrkA-positive cells or elicit pain behaviors in mice. NGF was coupled to the photosensitizer IRDye700DX phthalocyanine (IR700) and injected subcutaneously. After near-

infrared illumination of the injected area, behavioral responses to nociceptive mechanical and sustained thermal stimuli, but not innocuous stimuli, were substantially reduced. Similarly, in models of inflammatory, osteoarthritic, and neuropathic pain, mechanical hypersensitivity was abolished for 3 weeks after a single treatment regime. We demonstrate that this loss of pain behavior coincides with the retraction of neurons from the skin which then reinnervate the epidermis after 3 weeks corresponding with the return of mechanical hypersensitivity. Thus NGF-mediated photoablation is a minimally invasive approach to reversibly silence nociceptor input from the periphery, and control pain and hypersensitivity to mechanical stimuli. Increasing attention is being paid to cognitive decline and mood disorders, such as depression, that dramatically increase in frequency with age. Many efforts are focused on the identification of molecules and pathways to treat these conditions. Here, we report a novel role for GDF11 in attenuating depression associated with advanced aging in mice. Systemic administration of GDF11 reverts the depression-like phenotype and memory decline in aged mice. These effects occur via a neurogenesis-independent pathway as GDF11 does not activate neurogenesis *in vivo* or neural stem cell differentiation into neuroblasts *in vitro*. In contrast, we show that GDF11 acts on neurons to enhance neuronal activity, thus restoring memory and counteracting a depression-like phenotype in aged mice within a few weeks of treatment. In accordance with these findings, direct intracerebroventricular infusion of GDF11 in the brain of aged mice improves memory and alleviates anxiety- and depression-like symptoms. Our findings provide evidence that GDF11 could be a potent candidate biomarker for future therapeutic strategies aimed at targeting depressive states and age-related cognitive decline and highlight a novel role for GDF11 in the regulation of age-related depression and the possibility to use in therapeutic interventions.

TREHALOSE INCREASES TFEB AND AUTOPHAGIC FLUX IN THE DORSAL HIPPOCAMPUS, AND PRODUCES CHANGES IN EXPLORATORY BEHAVIOUR IN OLD MICE.

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Miguel Del Angel[1], Anne Albrecht[2], Oliver Stork[1]
[1]OVGU, Institute Of Biology, Magdeburg, Germany, [2]Institute of Anatomy, Neuroanatomy, Magdeburg, Germany

Ageing is associated with chronic dysregulation of autophagy, that if restored, has been suggested as therapeutic for treating neurodegenerative diseases and normal cognitive decline associated with age. Trehalose is a disaccharide that reduces protein aggregates in neurons, and although its mechanism of action is not yet completely understood, there is evidence that this effect is mediated through the upregulation of autophagy, partially through the activation of the transcription factor EB (TFEB) controlling lysosome biogenesis. Here we tested whether chronic intake of trehalose can modulate autophagy in the hippocampus of aged mice and improve spatial memory. Trehalose was administered in a concentration of 2.2% in the drinking water to young & old C57BL/6Jc mice, during which a battery of behavioural tests aimed to investigate changes in spatial learning was performed. Even though spatial learning seemed unaffected in the Morris water maze task (MWM), trehalose produced a decrease in the use of egocentric exploratory strategies, a staple of typical spatial memory acquisition, and resulted in a decreased permanence in the escape quadrant of the MWM during the probe trial, specifically in the aged animals. The changes in behavioral performance were associated with increased TFEB protein levels, as well as autophagic flux in the dorsal hippocampus. Our results indicate that during ageing, autophagy might be easily modulated in the dorsal hippocampus by trehalose, posibly in a TFEB dependent manner, and that this modulation produces changes in navigation skills, possibly affecting spatial memory. This work is supported by the German Research Foundation, RTG 2413 SynAGE.

Antibiotic-induced gut dysbiosis leads to activation of microglia and impairment of cholinergic gamma oscillations in the hippocampus.
Antibiotics are widely applied for the treatment of bacterial infections, but their long-term use may lead to gut flora dysbiosis and detrimental effects on brain physiology, behavior as well as cognitive performance. Still, a striking lack of knowledge exists concerning electrophysiological correlates of antibiotic-induced changes in gut microbiota and behavior. Here, we investigated changes in the synaptic transmission and plasticity together with behaviorally-relevant network activities from the hippocampus of antibiotic-treated mice. Prolonged antibiotic treatment led to a reduction of myeloid cell pools in bone marrow, circulation and those surveilling the brain. Circulating Ly6C inflammatory monocytes adopted a proinflammatory phenotype with increased expression of CD40 and MHC II. In the central nervous system, microglia displayed a subtle activated phenotype with elevated CD40 and MHC II expression, increased IL-6 and TNF production as well as with an increased number of Iba1 + cells in the hippocampal CA3 and CA1 subregions. Concomitantly, we detected a substantial reduction in the synaptic transmission in the hippocampal CA1 after antibiotic treatment. In line, carbachol-induced cholinergic gamma oscillation were reduced upon antibiotic treatment while the incidence of hippocampal sharp waves was elevated. These alterations were associated with the global changes in the expression of neurotrophin nerve growth factor and inducible nitric oxide synthase, both of which have been shown to influence cholinergic system in the hippocampus. Overall, our study demonstrates that antibiotic-induced dysbiosis of the gut microbiome and subsequent alteration of the immune cell function are associated with reduced synaptic transmission and gamma oscillations in the hippocampus, a brain region that is critically involved in mediation of innate and cognitive behavior.

The Presynaptic Scaffold Protein Bassoon in Forebrain Excitatory Neurons Mediates Hippocampal Circuit Maturation: Potential Involvement of TrkB Signalling.
A presynaptic active zone organizer protein Bassoon orchestrates numerous important functions at the presynaptic active zone. We previously showed that the absence of Bassoon exclusively in forebrain glutamatergic presynapses (cKO) in mice leads to developmental disturbances in dentate gyrus (DG) affecting synaptic excitability, morphology, neurogenesis and

related behaviour during adulthood. Here, we demonstrate that hyperexcitability of the medial perforant path-to-DG (MPP-DG) pathway in cKO mice emerges during adolescence and is sustained during adulthood. We further provide evidence for a potential involvement of tropomyosin-related kinase B (TrkB), the high-affinity receptor for brain-derived neurotrophic factor (BDNF), mediated signalling. We detect elevated TrkB protein levels in the dorsal DG of adult mice (~3-5 months-old) but not in adolescent (~4-5 weeks-old) mice. Electrophysiological analysis reveals increased field-excitatory-postsynaptic-potentials (fEPSPs) in the DG of the adult, but not in adolescent cKO mice. In line with an increased TrkB expression during adulthood in cKO, blockade of TrkB normalizes the increased synaptic excitability in the DG during adulthood, while no such effect was observed in adolescence. Accordingly, neurogenesis, which has previously been found to be increased in adult cKO mice, was unaffected at adolescent age. Our results suggest that Bassoon plays a crucial role in the TrkB-dependent postnatal maturation of the hippocampus.

Aims: Resilience describes the ability to preserve cognition, irrespective of the level of neuropathological hallmarks of Alzheimer's disease (AD). Cognitive resilience accounts for clinical heterogeneity state of patients and is certainly responsible of the translational failures of drugs' efficacy. We aimed here to investigate the cerebral correlates of cognitive resilience in a preclinical model of AD. Methods: Adult male Wistar and LOU/c/jall rats were exposed to a chronic cerebral infusion of soluble human beta-amyloid peptide 1-42 (15µM; AB42 groups; n=10 per strain) or vehicle solution (CTR groups; n=10 per strain) for 4 weeks (Alzet pumps 2ML4; 2.5 µl/hour). Using a battery of behavioural tests (elevated-plus maze, Y-maze, object recognition, Morris water maze), cognitive changes were then investigated followed by *ex vivo* cerebral analysis (immunohistochemistry and western-blot). Results: AB42-treated animals groups exhibited higher anxiety-like behaviour, whatever the strain considered. Besides, AB42 infusion induced working memory deficit, both in Wistar and LOU/c/jall, compared to their respective control. Conversely, no spatial memory impairment was observed. Finally, Wistar rats but not LOU/c/jall rats, showed recognition memory impairments following the AB42 infusion. At cellular and molecular levels, AB42 infusion induced hippocampal neuroinflammation and altered the hippocampal mTORC1 pathway in both rat strains. Conclusions: Already described as a model of successful aging, LOU/c/jall rats showed here a cognitive resilience in a model of AD mimicking pathology. A better understanding of the neurobiological mechanisms behind such resilience may afford new insights in the search for new therapeutic targets for AD.

VULNERABILITY OF SPATIAL PATTERN SEPARATION IN A TRANSGENIC MOUSE MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Aims: Alzheimer's disease (AD) is the most common cause of dementia and remains incurable. This age-related neurodegenerative disorder is characterized by early episodic and spatial memory decline associated with progressive hippocampus disturbances. Recent clinical data suggest that impairment of Spatial Pattern Separation function (SPSf), which allows the encoding and storage of episodic spatial information, could be an indicator of the early stages of AD. We aimed here to assess the time course of SPSf decline in a transgenic mouse model of amyloidogenesis to further investigate the underlying brain mechanisms. Methods: Performances of male wild-type (n = 18) and 5xFAD (n = 19) mice were assessed from 5 months of age in two behavioral tasks requiring SPSf. The first task was based on object recognition in an open field. The second task, which display a higher translational value, was based on the discrimination of visual stimuli using a touchscreen system. Results: Compared to the wild-type mice, a visual discrimination deficit was observed in 5-month old 5xFAD mice in the object recognition paradigm. Such discrimination deficit was not observed in the touchscreen-based paradigm. Our results indicate an early SPSf vulnerability in our model of AD pathology that depends on the behavioral task used. This discrepancy may be explained by the involvement of distinct cognitive and cerebral processes in the two tasks. Conclusion: Our work opens up the possibility of examining the early neurobiological processes involved in episodic memory decline and may help to propose new therapeutic strategies in the context of AD.

Background: 15 million infants are born prematurely every year, 40% of the time following maternal infections. The resulting neuroinflammatory processes affecting these newborns are driven by glial cells' reactivity (microglia and astrocytes) and increase the onset of brain lesions collectively termed Encephalopathy of Prematurity (EoP). EoP is associated with neurodevelopmental disorders in children and, in recent studies, with mental deficits such as mood disorders in young adults. Evidence demonstrated that long after initial reactivity, glial cells are keener to react exaggeratedly to later inflammatory stimuli, most probably through cellular priming. Recent literature focusing on the normal aging brain highlighted a low-grade chronic inflammatory state playing a potential role in the brain's susceptibility to neurodegeneration. Glial cells primed by perinatal inflammation could therefore increase the age-related inflammation state leading to early aging. Aims: We sought to determine whether a perinatal inflammatory challenge could accelerate the brain aging trajectory. Methods: This study is based on a mouse model of perinatal inflammation responsible for EoP-like lesions. Months later the onset of EoP, in middle-aged mice, we used transcriptomic (*RNA sequencing*), functional (Ultra-fast Doppler imaging, flow cytometry, histology), and behavioral analyses (open-field, 3-chamber test…) to evaluate the impact of perinatal inflammation on age-related inflammation and neuronal impairments, including functional brain connectivity and its behavioral consequences. Results: Our results showed signs of ongoing inflammation and glial reactivity while brain connectivity defects were recorded in middle-aged mice exposed to perinatal inflammation. Conclusion: Preliminary data tended to confirm long-term consequences of perinatal inflammation suggesting early brain aging.

Introduction: The immune system and the central nervous system (CNS) are each in direct contact with the other organs of the body, though their interconnection is only starting to be fully appreciated. During the crosstalk between the CNS and the immune system, neurotransmitters present in the local tissue environments influence innate and adaptive immune responses. Interestingly, recent evidence identified hypothalamic neurons as responsible for regulating splenic innervation. In Alzheimer's disease, the hypothalamic nuclei show a substantial decrease in neuronal populations, nevertheless, to our knowledge, the impact and consequences of an impairment in the neuroimmune crosstalk in AD were never addressed so far. **Methods:** To test the role of splenic innervation in animal models of AD (5xFAD) and WT mice, we adapted a surgical denervation procedure treating splenic nerve plexuses with alcohol before they enter the spleen, selectively ablating the innervation of the spleen without affecting other organs. Subsequently, we tested the cognitive performance of all mice, and we studied their immune landscape in the spleen, blood and brain through high-dimensional single-cell mass cytometry. **Results:** Loss of the sympathetic innervation impair the production of Interleukin-4 from CD4+ splenocytes, alters microglia phenotype, and significantly accelerates cognitive loss in 5xFAD mice with no effect on WT mice. **Conclusions:** These results show that the innervation of peripheral organs plays a crucial role in the development of a proper immune response, which in turn is needed to limit CNS pathology and support brain functioning in the context of neurodegenerative disorders.

Immune cell compartmentalization for brain surveillance and protection.
For decades, it was commonly accepted that the brain is secluded from peripheral immune activity and is self-sufficient for its maintenance and repair. This simplistic perception was based on the presence of resident immune cells, the microglia, and barrier systems within the brain, and the assumption that the central nervous system (CNS) lacks lymphatic drainage. This view was revised with the discoveries that higher functions of the CNS, homeostasis and repair are supported by peripheral innate and adaptive immune cells. The findings of bone marrow-derived immune cells in specialized niches, and the renewed observation that a lymphatic drainage system exists within the brain, further contributed to this revised model. In this Review, we describe the immune niches within the brain, the contribution of professional immune cells to brain functions, the bidirectional relationships between the CNS and the immune system and the relevance of immune components to brain aging and neurodegenerative diseases.

Extracellular vesicles in neurodegenerative diseases.
Extracellular vesicles (EVs) are released by all neural cells, including neurons, oligodendrocytes, astrocytes, and microglia. The lack of adequate technology has not halted neuroscientists from investigating EVs as a mean to decipher neurodegenerative disorders, still in search of comprehensible pathogenic mechanisms and efficient treatment. EVs are thought to be one of ways neurodegenerative pathologies spread in the brain, but also one of the ways the brain tries to displace toxic proteins, making their meaning in pathogenesis uncertain. EVs, however do reach biological fluids where they can be analyzed, and might therefore constitute clinically decisive biomarkers for neurodegenerative diseases in the future. Finally, if they constitute a physiological inter-cell communication system, they may represent also a very specific drug delivery tool for a difficult target such as the brain. We try to resume here available information on the role of EVs in neurodegeneration, with a special focus on Alzheimer's disease, progressive multiple sclerosis, amyotrophic lateral sclerosis,

and Huntington's disease.

Subclinical anterior optic pathway involvement in early multiple sclerosis and clinically isolated syndromes.
Optical coherence tomography (OCT) is gaining increasing relevance in the assessment of patients with multiple sclerosis. Converging evidence point to the view that neuro-retinal changes, in eyes without acute optic neuritis, reflect inflammatory and neurodegenerative processes taking place throughout the CNS. The present study aims at exploring the usefulness of OCT as a marker of inflammation and disease burden in the earliest phases of the disease. Thus, a cohort of 150 consecutive patients underwent clinical, neurophysiological and brain MRI assessment as well as lumbar puncture as part of their diagnostic workup for a neurological episode suggestive of inflammatory CNS disorder; among those 32 patients had another previous misdiagnosed episode. For the present study, patients also received a visual pathway assessment (OCT, visual evoked potentials, visual acuity), measurement of CSF inflammatory markers (17 cytokines-chemokines, extracellular vesicles of myeloid origin), and dosage of plasma neurofilaments. Subclinical optic nerve involvement is frequently found in clinically isolated syndromes by visual evoked potentials (19.2%). OCT reveals ganglion cell layer asymmetries in 6.8% of patients; retinal fibre layer asymmetries, despite being more frequent (17.8%), display poor specificity. The presence of subclinical involvement is associated with a greater disease burden. Second, ganglion cell layer thinning reflects the severity of disease involvement even beyond the anterior optic pathway. In fact, the ganglion cell layer in eyes without evidence of subclinical optic involvement is correlated with Expanded Disability Status Scale, low contrast visual acuity, disease duration, brain lesion load, presence of gadolinium enhancing lesions, abnormalities along motor and somatosensory evoked potentials, and frequency of CSF-specific oligoclonal bands. Third, the inner nuclear layer thickens in a post-acute (1.1-3.7 months) phase after a relapse, and this phenomenon is counteracted by steroid treatment. Likewise, a longitudinal analysis on 65 patients shows that this swelling is transient and returns to normal values after 1 year follow-up. Notwithstanding, the clinical, MRI, serological and CSF markers of disease activity considered in the study are strictly associated with one another, but none of them are associated with the inner nuclear layer. Our findings challenge the current hypothesis that the inner nuclear layer is an acute phase marker of inflammatory activity. The present study suggests that instrumental evidence of subclinical optic nerve involvement is associated with a greater disease burden in clinically isolated syndrome. Neuro-retinal changes are present since the earliest phases of the disease and yield important information regarding the neurodegenerative and inflammatory processes occurring in the CNS.

SIRT1-DEPENDENT AUTOPHAGY AS A NOVEL THERAPY FOR AGE-RELATED MEMORY DECLINE

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

David Romeo-Guitart, François Mailliet, Manon Rivagorda, Franck Oury
INSERM U1151 - Université de Paris, Institut Necker Enfants Malades (inem), Paris, France

Over the last years, Sirtuins (SIRT) have been directly linked to the maintenance of neuronal homeostasis and functions throughout life. Among the SIRT1-7 members, the SIRT1 has been described as a mediator of the well-ageing of the whole organism. Importantly, its anti-ageing effects require the cellular degradative process called autophagy. In that way, recent evidence indicate that autophagy is necessary for memory formation and reverses age-related memory loss. However, the role of SIRT1-dependent autophagy in the maintenance of memory fitness during ageing remains unknown. We have characterized the function of SIRT1 enzyme by means of gene expression, protein levels, phosphorylation state and deacetylase activity, observing that it is reduced in the hippocampus (HpC) of aged mice. We then modulated SIRT1 activity in the HpC by genetic and pharmacological approaches in young and aged mice, observing that it is essential for novel memory formation and integration, and its boosting ameliorates age-related memory decline. That phenotype is accompanied by restoration of autophagy machinery in the aged HpC. All these data open novel therapeutic avenues to rejuvenate cognitive fitness by modulating SIRT1-dependent autophagy.

LINKING INTER-INDIVIDUAL DIFFERENCES IN COGNITIVE FUNCTION TO RNAOME HETEROGENEITY

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Aditi Methi, M. Sadman Sakib, Lalit Kaurani, Jonathan Cortés Silva, Jiayin Zhou, Susanne Burkhardt, Tonatiuh Pena, Vakhtang Elerdashvili, Andre Fischer
German Center for Neurodegenerative Diseases (DZNE), Dept. For Epigenetics And Systems Medicine In Neurodegenerative Diseases, Göttingen, Germany

Cognitive functions decline with age but a majority of these changes occur in a highly selective and subtle manner. Moreover, there exists a high degree of variability in neurocognitive and memory function among healthy aged individuals. Thus, some individuals undergo healthy cognitive aging while others eventually develop dementia, but the underlying mechanisms are not well understood. This project aims to elucidate which specific adaptive or compensatory responses sustain healthy cognitive function in the brains of aged individuals. Our hypothesis is that differences in gene-expression patterns play a role. Thus, we used the Morris water maze (MWM) test as a standard task paradigm for assessing spatial learning and memory in 60 C57BL/6J wild-type healthy aged mice (16-months old). Mice were trained in the MWM for 6 days. We developed a novel spatial learning index termed the 'cognitive score' as an assessment of the cognitive ability of a mouse, based on various metrics extracted from its MWM performance by a neural-network algorithm. This allowed us to rank mice based on their individual cognitive scores and select the best and worst performers (called 'good' or 'bad' learners) for further analyses. Coding and non-coding RNA expression data from total RNA sequencing (from hippocampus and cortical tissue samples) from selected mice were analysed to link RNAome changes to the cognitive score. Our current data suggest that differences in cognitive aging are accompanied by very subtle changes in gene and non-coding RNA expression. Candidate RNAs and their downstream processes will be validated using functional assays.

[1]Université de Strasbourg, CNRS, Laboratoire De Neurosciences Cognitives Et Adaptatives, Umr 7364, Strasbourg, France, [2]University of Strasbourg, Icube Lab, Strasbourg, France, [3]University Hospital of Strasbourg, Department Of Biophysics And Nuclear Medicine, Strasbourg, France

Background: Cognitive decline in preclinical Alzheimer's disease (AD) is more pronounced in women than in men. However, only a few studies explored gender-specificity in AD at this early stage, and underlying mechanisms remain unclear. **Objective**: Our study aims at identifying sex-specific cognitive and brain network biomarkers associated to preclinical stage in AD. **Methodology**: We designed a longitudinal study to explore a new preclinical model, the *AppNL-F/MAPT*double knock-in (dKI) mouse, humanized for *App* and *MAPT* genes. We combined recognition memory tests with functional and structural brain Magnetic Resonance Imaging (MRI) to explore the relationship between sex-specific cognitive impairment and connectivity signatures associated to preclinical AD pathology. **Results**: At 2 months, dKI female mice did not detect the novel object (p=0,0003) in the Novel Object Recognition test compared to WT mice. WT and dKi male mice significantly explored the novel object (p=0,98). Therefore, females dKi mice presented memory deficits at a very early age in long-term memory tests when males didn't. **Conclusions**: Using subtle memory tests on a new mouse model of AD at early onset of AD, our study highlighted early cognitive impairments in female mice but not in male. Therefore, the dKI mouse model showed good promises in the characterization of the female vulnerability, especially at early onset AD. Sex-specific alteration in memory networks will be further explored using functional and structural MRI.

VOLUNTARY WHEEL RUNNING IN OLD C57BL/6 MICE REDUCES AGE-RELATED INFLAMMATION IN THE COLON BUT NOT IN THE BRAIN

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Marie-Luise Ederer[1], Madlen Günther[1], Lena Best[2], Julia Linder[1], Christoph Kaleta[2], Otto W. Witte[1], Rowena Simon[1], Christiane Frahm[1]
[1]University Hospital Jena, Neurology, Jena, Germany, [2]Kiel University, Institute For Experimental Medicine, Kiel, Germany

Inflammation is considered a possible cause of cognitive decline during aging. This study investigates the influence of physical activity and social isolation in old mice on their cognitive functions and inflammation. The Barnes maze task was performed to assess spatial learning and memory in 3, 9, 15, 24, and 28 months old male C57BL/6 mice as well as following voluntary wheel running (VWR) and social isolation (SI) in 20 months old mice. Inflammatory gene expression was analyzed in hippocampal and colonic samples by qPCR. Cognitive decline occurs in mice between 15 and 24 months of age. VWR improved cognitive functions while SI had negative effects. Expression of inflammatory markers changed during aging in the hippocampus (*Il1a*/*Il6*/*S100b*/*Iba1*/*Adgre1*/*Cd68*/*Itgam*) and colon (*Tnf*/*Il6*/*Il1ra*/*P2rx7*). VWR attenuates inflammaging specifically in the colon (*Ifng*/*Il10*/*Ccl2*/*S100b*/*Iba1*), while SI regulates intestinal *Il1b* and *Gfap*. Inflammatory markers in the hippocampus were not altered following VWR and SI. The main finding of our study is that both the hippocampus and colon exhibit an increase in inflammatory markers during aging, and that voluntary wheel running in old age exclusively attenuates intestinal inflammation. Based on the existence of the gut-brain axis, our results extend therapeutic approaches preserving cognitive functions in the elderly to the colon.

THE ROLE OF TELOMERES IN NEURONAL AGING

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Marco Raffaelli[1], Eric Gilson[1], Franck Oury[2]
[1]Institute for Research on Cancer and Aging, Nice (IRCAN), Nice University, Cnrs Umr7284/inserm U1081, Faculty Of Medicine, Nice 06107, France, Nice, France, [2]INSERM U1151 - Université de Paris, Institut Necker Enfants Malades (inem), Paris, France

Telomere shortening is a developmentally regulated process leading mitotic cells to senescence. Whether changes in telomere and its associated protein complex Shelterin are involved in post-mitotic cell ageing remains elusive. Our group discovered that the expression of TRF2 (key Shelterin subunit) decreases with age and its downregulation in postmitotic myotubes leads to hallmarks of aging such as mitochondrial dysfunction and increased ROS production, but not to increased DNA damage. We set to investigate whether the same mechanisms occurred in the neuron, another type of long-lived post-mitotic cell. By means of *in vitro* and *in vivo* approaches assessing the effect of telomere alteration on the neuronal phenotype, we aimed at obtaining new insight on telomere dynamics with respect to neuronal aging. The deep understanding of these mechanisms might lead to the discovery of therapies against age-related pathologies and to their prevention.
The data obtained show that TRF2 neuronal expression declines with aging. Moreover, its downregulation in cultured primary neurons increases the rate of telomeric DNA damage and affects the vesicular axonal transport, which is pivotal for neuronal function. Furthermore, *in vivo* TRF2 downregulation via genetic tools impairs memory and learning processes as assessed via behavioural tests. These findings show that different types of post-mitotic cells age to different mechanisms, and that TRF2 neuronal decline is upstream of well-known aging phenomena. Our results suggest a modification of the paradigm that sees age-driven telomere changes uniquely upstream of mitotic cell aging, envisioning a wider role for telomeres in aging across the mitotic-postmitotic boundaries.

Even though Alzheimer's disease (AD) is the most common cause of dementia, it is still currently incurable. Recently, many hypotheses have stablished a clear relationship among inflammation and metabolic alterations with AD progression, becoming a potential target to stop neurodegeneration and remain in a cognitive resilient stage. Particularly, Licochalcone-A (LCA) has been described as an emergent drug with multiple therapeutical properties, such as an antidiabetic and anti-inflammatory effect, but little is known about the mechanism underlying LCA's neuroprotective effect. Therefore, this study aims to determinate the potential protective effect of LCA against hallmarks of AD. To perform this study, six-month-old male APPswe/PS1dE9 (APP) and C57BL/6J (WT) mice were intraperitoneally treated with saline or LCA at a dose of 15 mg/kg/day, three times per week for one month. Those mice were divided into 4 different experimental groups; WT Saline, WT LCA, APP Saline and APP LCA. Before sacrificing, insulin and glucose tolerance were analysed to determinate metabolic alterations and behavioural tests were performed to evaluate memory loss. Afterwards, hallmarks related to synapsis, metabolism and neuroinflammation were studied in the hippocampus. The present data reports the beneficial effect of LCA regarding to cognitive decline observed in AD by conferring neuroprotection against neuroinflammation and metabolic disruptions, improving dendritic spine deterioration and other synaptic hallmarks. All together contribute to the maintenance of cognitive resilience avoiding the development of AD. In conclusion, our results suggest that LCA could be a potential treatment against neurodegeneration by promoting a cognitive resilient stage of the disease.

METFORMIN AS A POTENTIAL ANTI-AGING THERAPY: TARGETING THE TRIPARTITE SYNAPSE

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Danai Katsere[1], Anke Müller[1,2], Anne Bayrhammer[2], Sabrina Keiper[1], Peter Landgraf[1], Daniela Dieterich[1,2]

With the rapidly growing aging population comes the impetus to develop strategies that alleviate age-related cognitive decline. Possible pharmacological agents to counteract brain aging are mostly neuron-focused, however astrocytes could be an interesting drug target as they are highly dynamic, crucially support as well as influence neuron function, and contribute to disease development and progression. The aim of this study is to investigate possible effects of pharmacological intervention on astrocyte-neuron interactions in normoglycemic conditions using metformin, with a focus on healthy aging. A well-established cell culture model was employed to assess the effect of 24-hour metformin treatment on neurons. In addition, a transgenic MetRS-Aldh1l1 mouse model, where mutated methionyl-tRNA synthetase (MetRS) is expressed solely in astrocytes, was used to assess the in vivo effects of metformin feeding on young, middle-aged and old mice. Our cell culture model revealed that metformin treatment had differing effects on protein translation and expression of key proteins involved in neuronal signalling and synaptic composition in mature (DIV23) and aged (DIV80) cultures. In mice, early indications show that 12 weeks of metformin feeding upregulated protein translation and glial fibrillary acidic protein (GFAP) expression in both young and old animals, however the effect was reversed in middle-aged animals. To conclude, metformin seems to have an impact on protein dynamics in astrocytes and neurons, and we aim to further elucidate how metformin alters astrocyte proteostasis and in turn synaptic protein expression during aging.

The brain utilizes between 20 to 25% of the available energy to ensure its proper function. Glucose, an important energy source for the brain, access the neuropil across the blood-brain barrier (BBB) and is transported into astrocytes, where it can be stored as glycogen. Astrocytes are the most abundant type of glial cell in the brain and play a crucial role in supporting neuronal metabolism. Lactate can be synthesized in astrocytes through glycogenolysis and then shuttled via monocarboxylate transporters (MCTs) to neurons to fuel their tricarboxylic acid (TCA) cycle. This mechanism, known as the astrocyte-neuron lactate shuttle (ANLS), is involved in learning and memory formation. Aging is associated with a decline of faculties such as memory, motor skills, and sensory perception, which are not caused by a substantial loss of neurons but rather changes at multiple levels (e.g., connectivity, morphology, white matter). Here, we aim to compare the glycogen distribution in layer I of the somatosensory cortex between young and aging mice. The visual analysis was done using a customized software to explore brain reconstructions at the nanometric level. Using the computational tool GLAM (Glycogen-derived Lactate Absorption Map), we inferred a probability map of the locations where astrocytic glycogen-derived lactate is most likely to access the surrounding neurites. We analyzed and compared these maps on axons, dendrites, boutons, and spines to hypothesize about single compartments' energy consumption. Our results indicate that aging brains have a more glycolytic metabolism, with fewer GLAM peaks facing mitochondria and smaller glycogen granules.

Astrocytes exert varied functions to support and maintain nervous system homeostasis, modulate neuronal signaling but also contribute to the nervous system impairments in aging and disease. Upto date, little is known about regional astrocyte diversity and functional specifications in subregions of the brain which is, in part, due to a lack of selective tools to approach astrocytes. Here, we developed an astrocyte-specific metabolic labeling strategy using Tamoxifen-inducible Aldh1l1-*Cre/*ERT2 mice that allow for highly specific expression of MetRS^{L274G} in astrocytes. The subsequent application of the Non-Canonical Amino Acid Tagging(NCAT) technology *in vivo* enabled us to identify newly synthesized proteins cell type-specifically in astrocytes. This model allows analysis of translation rates in different brain regions as well as isolation of astrocytic proteins and subsequent Mass Spectrometry. Bioinformatic analyses verify the astrocytic origin of identified proteins and subsequent gene enrichment analysis reveals an abundant involvement in metabolic processes with little variation among brain regions. We further analyzed the protein turnover rates of astrocytes in subregions of the young(2 months) and old(24 months) mouse hippocampus. Astrocytes in the CA1 region showed higher translational activity that correlates with higher arborization compared to CA3 and DG astrocytes in younger ones. Aged hippocampal astrocytes revealed significantly higher protein turnover rates but contrastingly shrunken and less arborized morphology in the CA1 and DG regions of the hippocampus compared to young mice, which could contribute to loss of synaptic support during aging. Taken together, these results advance the knowledge of regional and age-dependent alterations in astrocyte protein dynamics and diversity.

AGE-RELATED EFFECTS ON EXPLORATION STRATEGIES DURING PROBABILISTIC REWARD LEARNING

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Jean-Baptiste De Saint Aubert[1], Elena Aprea[1,2], Marie-Léa Maury[1], Angelo Arleo[1]
[1]Sorbonne Université, INSERM, CNRS, Institut De La Vision, Paris, France, [2]Scuola Superiore Sant'Anna, The Biorobotics Institute, Pisa, Italy

Aims Decision-making often relies on a balance between exploration and exploitation. Behavioral studies of age-related effects on decision-making in humans have reported that healthy aging tends to shift the exploration/exploitation trade-off toward exploitation, coinciding with the use of less demanding cognitive processes. However, little is known on how age affects exploration strategies in uncertain environments. With this study, we aim to characterize the age-related differences between strategies relying on random (i.e., value-based or value-free) versus directed (i.e., uncertainty-driven) exploration. Methods We used 2- and 4-armed bandit tasks in a lab-based experiment with 34 subjects (17 young, 25.4 ± 4.6 y.o., and 17 older adults, 74.6 ± 3.8 y.o., recruited from the SilverSight cohort at the Vision Institute), and in an online study with 382 subjects (191 young, 22.0 ± 2.0 y.o., and 191 older adults, 73.7 ± 3.4 y.o., recruited through the Prolific platform). Participant were instructed to maximize their payoffs by repeatedly choosing between options to obtain rewards determined by a gaussian random walk. A reinforcement learning framework was employed to model subjects' task-solving policies. Results Older adults showed stronger individual differences than young adults and their strategies where better predicted by model-free policies. Unexpectedly, computational modeling showed that they explored no less than young adults, but relied primarily on random value-free exploration, whereas young adults mainly used directed exploration. Conclusions Healthy aging shapes the exploration/exploitation balance toward more random explorative strategies. A follow-up study will investigate age-related differences in exploration strategies during ecological spatial learning and goal-oriented navigation.

NEURAL CORRELATES OF AFFECTIVE EMPATHY IN AGING: A MULTIMODAL IMAGING, MULTIVARIATE APPROACH

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Maryam Ziaei[1], Lena Oestreich[2], Jonas Persson[3], David Reutens[4], Natalie Ebner[5]
[1]Norwegian University of Science and Technology (NTNU), Kavli Institute For Systems Neuroscience, Trondheim, Norway, [2]UQ Centre for Clinical Research, Faculty Of Medicine, Brisbane, Australia, [3]Center for Lifespan Developmental Research, School Of Law, Psychology And Social Work,, Orebro, Sweden, [4]Centre for advanced imaging, University Of Queensland, Brisbane, Australia, [5]Department of Psychology, University Of Florida, Gainesville, United States of America

Various aspects of social cognition change as we age and can critically impact cognitive functioning among older adults. Empathy is one such social-cognitive capacity that undergoes age-related change. Previous work has started to identify brain correlates of empathy, but currently not well understood is the structural and functional neurocircuitry underlying age-related differences in empathy. To address this research gap, this study delineates brain structural and functional networks that subserve affective empathic response in younger and older adults using a modified version of the Multifaceted Empathy Task (MET). The MET differentiates affective from cognitive components of empathy, and we included both positive and negative emotions. Combining multimodal neuroimaging (functional magnetic resonance and diffusion-weighted imaging) with multivariate partial least square analysis resulted in three novel findings for affective empathy in older but not younger adults: *(a)* faster empathic responding to negative emotions was related to greater fractional anisotropy of the anterior cingulum and greater functional activity of the anterior cingulate network; *(b)* empathic responding to positive emotions was related to greater fractional anisotropy of the posterior cingulum and greater functional activity of the posterior cingulate network, and *(c)* faster empathic responding to both positive and negative emotions was related to greater fractional anisotropy of the left uncinate fasciculus and greater functional activity in a widespread anterior cingulate network that resembled the default mode network. These findings reflect a posterior-to-anterior-shift in aging (PASA), as previously observed in cognitive aging, regarding emotional valence suggesting an extension of the PASA model to higher-order social-cognitive processes.

AGED MALE RATS SHOW IMPAIRED COGNITIVE FLEXIBILITY BUT NO CHANGE IN MOTIVATION

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Megan Jackson[1], Stafford Lightman[2], Becky Conway-Campbell[2], Emma Robinson[1]
[1]University of Bristol, Physiology, Pharmacology And Neuroscience, Bristol, United Kingdom, [2]University of Bristol, Translational Health Sciences, Bristol, United Kingdom

Aims: Apathy is a psychiatric syndrome that is common in otherwise-healthy ageing. It consists of behavioural, cognitive and emotional domains. There is no agreed treatment approach for apathy, which may be driven by a lack of translational preclinical apathy models. We aimed to assess whether aged rats displayed a behavioural profile relevant to the behavioural and cognitive domains of human apathy. **Methods**: N=10 young (4-months-old) and aged (21-months-old) Sprague-Dawley male rats underwent a battery of behavioural tests hypothesised to map onto aspects of behavioural and cognitive apathy. The effort for reward (EfR) and progressive ratio (PR) tasks were used to assess physical effort-based motivation. The sucrose preference test (SPT) was used to assess reward sensitivity. A bowl-digging and operant-based probabilistic reversal learning (PRL) tasks were used to assess cognitive flexibility in an ethological and non-ethological context. **Results:** Aged rats showed no impairment in the EfR, PR, or SPT tasks. However, they showed a profound impairment in cognitive flexibility in the bowl-digging version of the PRLT. This deficit was specific to a reduction in win-stay behaviour. This deficit did not occur in the operant version of the task. **Conclusion:** Aged rats showed a specific deficit in cognitive flexibility associated with positive but not negative feedback. These effects were not related to any changes in physical effort or effort-based decision-making. The difference in findings between the bowl-digging and operant versions of the PRL suggests a greater sensitivity to changes associated with ageing using tasks based on more ethologically relevant cues.

Evidence for deficits in behavioural and physiological responses in aged mice relevant to the psychiatric symptom of apathy. Apathy is widely reported in patients with neurological disorders or post viral infection but is also seen in otherwise-healthy aged individuals. This study investigated whether aged male mice express behavioural and physiological changes relevant to an apathy phenotype. Using measures of motivation to work for reward, we found deficits in the progressive ratio task related to rate of responding. In an effort-related decision-making task, aged mice were less willing to exert effort for high value reward. Aged mice exhibited reduced reward sensitivity but also lower measures of anxiety in the novelty supressed feeding test and an attenuated response to restraint stress with lower corticosterone and reduced paraventricular nucleus c-fos activation. This profile of affective changes did not align with those observed in models of depression but suggested emotional blunting. In a test of cognition (novel object recognition), aged mice showed no impairments, but activity was lower in a measure of exploration in a novel environment. Together, these data suggest aged mice show changes across the domains of motivated behaviour, reward sensitivity and emotional reactivity and may be a suitable model for the pre-clinical study of the psychiatric symptom of apathy.

The use of ball pits and playpens in laboratory Lister Hooded male rats induces ultrasonic vocalisations indicating a more positive affective state and can reduce the welfare impacts of aversive procedures.
The advancement and quality of science rely on research that is robust and unbiased in its experimental design, execution, analysis, and reproducibility. In preclinical research, a better understanding of animal emotions and refinement of their husbandry, housing, and handling are important goals in providing good animal welfare in a laboratory setting which underpins rigorous research quality. Induction of positive emotional state in animals is a key component of their well-being, and one approach is to increase their environmental complexity using, for example, ball pits or playpens in rats. In this study, we recorded 50 kHz ultrasonic vocalisations (USVs) during animals' exposure to the ball pit and playpen. We have previously shown that 50 kHz USVs provide a graded and quantifiable measure of an animal's emotional state, and here find that access to the ball pit and playpen increases 50 kHz USVs, indicative of a more positive affective state. Using our affective bias test (ABT) we next quantified the animals' emotional response to an aversive intervention and whether this could be attenuated by

access to a playpen. The playpen exposure completely mitigated the negative affective state induced by an anxiogenic drug when compared with animals who experienced the drug in the home cage. Together, these findings suggest ball pits and playpens provide a simple and effective method to improve the welfare of laboratory rats and reduce the cumulative suffering they experience from their housing conditions and minor, aversive procedures.

AGE-DEPENDENT DYNAMICS IN ACUTE AND CHRONIC STRESS-INDUCED FOSB/ΔFOSB CONTENT IN THE EXTENDED AMYGDALA, HYPOTHALAMIC PARAVENTRICULAR, HABENULAR, CENTRALLY-PROJECTING EDINGER-WESTPHAL AND DORSAL RAPHE NUCLEI IN MALE RATS

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

László Ákos Kovács[1,2], Nóra Füredi[1], Balázs Ujvari[2], Abolfazl Golgol[2], Balázs Gaszner[1,2]

The expression of early responding gene products (FOS, FOSB, ΔFOSB) can be activated by acute and chronic stimuli resulting in an increase of nuclear FOS protein content, that appears to decline by aging. Extended amygdala exhibits high basal FOSB/ΔFOSB content which does not change in response to acute restraint stress (ARS) or chronic variable mild stress (CVMS). Contrarily, the FOSB/ΔFOSB content increases upon CVMS in the lateral habenula (LHb), hypothalamic paraventricular nucleus (PVN), centrally-projecting Edinger-Westphal nucleus (EWcp) and dorsal raphe nucleus (DR). The age-dependent dynamics of FOSB/ΔFOSB reaction to stress is unknown. We aimed to semi-quantify the FOSB/ΔFOSB content of extended amygdala nuclei; habenula, PVN, EWcp, DR and the somatosensory cortex (S1) in the course of aging. Eight age groups (1-month-old (M), 1.5M, 2M, 3M, 6M, 12M, 18M, 24M) of rats were exposed to a single ARS versus controls. Rats in six age groups (2M, 3M, 6M, 12M, 18M, 24M) were subjected to CVMS. The FOSB/ΔFOSB immunoreactivity was a function of age in all groups. ARS increased the FOSB/ΔFOSB immunoreactivity in all nuclei. Only ventral and fusiform divisions of the bed nucleus of the stria terminalis (BNST) and PVN reacted throughout the examined lifespan. CVMS did not increase the FOSB/ΔFOSB immunoreactivity in BLA, oval and dorsolateral division of BNST, and S1. Corresponding to our previous observations on FOS, the FOSB/ΔFOSB response to stress decreased with age. Only the PVN exerted a sustained age-independent FOSB/ΔFOSB, which may reflect the long-lasting adaptation response and plasticity of neurons that maintain the stress (mal)adaptation.

Neurodegeneration in the centrally-projecting Edinger-Westphal nucleus contributes to the non-motor symptoms of Parkinson's disease in the rat.
The neuropathological background of major depression and anxiety as non-motor symptoms of Parkinson's disease is much less understood than classical motor symptoms. Although, neurodegeneration of the Edinger-Westphal nucleus in human Parkinson's disease is a known phenomenon, its possible significance in mood status has never been elucidated. In this work we aimed at investigating whether neuron loss and alpha-synuclein accumulation in the urocortin 1 containing (UCN1) cells of the centrally-projecting Edinger-Westphal (EWcp) nucleus is associated with anxiety and depression-like state in the rat.

Corticotropin-Releasing Factor-Producing Cells in the Paraventricular Nucleus of the Hypothalamus and Extended Amygdala Show Age-Dependent FOS and FOSB/DeltaFOSB Immunoreactivity in Acute and Chronic Stress Models in the Rat.
Corticotropin-releasing factor (CRF) immunoreactive (ir) neurons of the paraventricular nucleus of the hypothalamus (PVN) play pivotal role in the coordination of stress response. CRF-producing cells in the central nucleus of amygdala (CeA) and oval division of the bed nucleus of stria terminalis (BNSTov) are also involved in stress adaptation and mood control. Immediate early gene products, subunits of the transcription factor activator protein 1 (AP1) are commonly used as acute (FOS) and/or chronic (FOSB/deltaFOSB) markers for the neuronal activity in stress research. It is well known that the course of aging affects stress adaptation, but little is known about the aging-related stress sensitivity of CRF neurons. To the best of our knowledge, the stress-induced neuronal activity of CRF neurons in the course of aging in acute and chronic stress models was not studied systematically yet. Therefore, the aim of the present study was to quantify the acute restraint stress (ARS) and chronic variable mild stress (CVMS) evoked neuronal activity in CRF cells of the PVN, CeA, and BNSTov using triple-label immunofluorescence throughout the whole lifespan in the rat. We hypothesized that the FOS and FOSB content of

CRF cells upon ARS or CVMS decreases with age. Our results showed that the FOS and FOSB response to ARS declined with age in the PVN-CRF cells. BNSTov and CeA CRF cells did not show remarkable stress-induced elevation of these markers neither in ARS, nor in CVMS. Exposure to CVMS resulted in an age-independent significant increase of FOSB/delta FOSB immunosignal in PVN-CRF neurons. Unexpectedly, we detected a remarkable stress-independent FOSB/deltaFOSB signal in CeA- and BNSTov-CRF cells that declined with the course of aging. In summary, PVN-CRF cells show decreasing acute stress sensitivity (i.e., FOS and FOSB immunoreactivity) with the course of aging, while their (FOSB/deltaFOSB) responsivity to chronic challenge is maintained till senescence. Stress exposure does not affect the occurrence of the examined gene products in CeA- and BNSTov-CRF cells remarkably suggesting that their contribution to stress adaptation response does not require AP1-controlled transcriptional changes.

Both Basal and Acute Restraint Stress-Induced c-Fos Expression Is Influenced by Age in the Extended Amygdala and Brainstem Stress Centers in Male Rats.
The hypothalamus-pituitary-adrenal axis (HPA) is the main regulator of the stress response. The key of the HPA is the parvocellular paraventricular nucleus of the hypothalamus (pPVN) controlled by higher-order limbic stress centers. The reactivity of the HPA axis is considered to be a function of age, but to date, little is known about the background of this age-dependency. Sporadic literature data suggest that the stress sensitivity as assessed by semi-quantitation of the neuronal activity marker c-Fos may also be influenced by age. Here, we aimed at investigating the HPA activity and c-Fos immunoreactivity 2 h after the beginning of a single 60 min acute restraint stress in eight age groups of male Wistar rats. We hypothesized that the function of the HPA axis (i.e., pPVN c-Fos and blood corticosterone (CORT) level), the neuronal activity of nine stress-related limbic areas (i.e., magnocellular PVN (mPVN), medial (MeA), central (CeA), basolateral nuclei of the amygdala, the oval (ovBNST), dorsolateral (dlBNST), dorsomedial (dmBNST), ventral and fusiform (fuBNST) divisions of the bed nucleus of the stria terminalis (BNST)), and two brainstem stress centers such as the centrally projecting Edinger-Westphal nucleus (cpEW) and dorsal raphe nucleus (DR) show age dependency in their c-Fos response. The somatosensory barrel cortex area (S1) was evaluated to test whether the age dependency is specific for stress-centers. Our results indicate that the stress-induced rise in blood CORT titer was lower in young age reflecting relatively low HPA activity. All 12 stress-related brain areas showed c-Fos response that peaked at 2 months of age. The magnitude of c-Fos immunoreactivity correlated negatively with age in seven regions (MeA, CeA, ovBNST, dlBNST, dmBNST, fuBNST and pPVN). Unexpectedly, the CeA, ovBNST and cpEW showed a considerable basal c-Fos expression in 1-month-old rats which decreased with age. The S1 showed a U-shaped age-related dynamics in contrast to the decline observed in stress centers. We conclude that the age- and brain area dependent dynamics in stress-induced neuronal activity pattern may contribute to the age dependance of the stress reactivity. Further studies are in progress to determine the neurochemical identity of neurons showing age-dependent basal and/or stress-induced c-Fos expression.

Construct and face validity of a new model for the three-hit theory of depression using PACAP mutant mice on CD1 background.
Major depression is a common cause of chronic disability. Despite decades of efforts, no equivocally accepted animal model is available for studying depression. We tested the validity of a new model based on the three-hit concept of vulnerability and resilience. Genetic predisposition (hit 1, mutation of pituitary adenylate cyclase-activating polypeptide, PACAP gene), early-life adversity (hit 2, 180-min maternal deprivation, MD180) and chronic variable mild stress (hit 3, CVMS) were combined. Physical, endocrinological, behavioral and functional morphological tools were used to validate the model. Body- and adrenal weight changes as well as corticosterone titers proved that CVMS was effective. Forced swim test indicated increased depression in CVMS PACAP heterozygous (Hz) mice with MD180 history, accompanied by elevated anxiety level in marble burying test. Corticotropin-releasing factor neurons in the oval division of the bed nucleus of the stria terminalis showed increased FosB expression, which was refractive to CVMS exposure in wild-type and Hz mice. Urocortin1 neurons became over-active in CMVS-exposed PACAP knock out (KO) mice with MD180 history, suggesting the contribution of centrally projecting Edinger-Westphal nucleus to the reduced depression and anxiety level of stressed KO mice. Serotoninergic neurons of the dorsal raphe nucleus lost their adaptation ability to CVMS in MD180 mice. In conclusion, the construct and face validity criteria suggest that MD180 PACAP HZ mice on CD1 background upon CVMS may be used as a reliable model for the three-hit theory.

GREY AND WHITE MATTER MICROSTRUCTURE PLAY COMPLEMENTARY ROLES SUPPORTING COGNITIVE PERFORMANCE IN ADOLESCENCE OF THE ABCD COHORT.

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Léa Michel, Rogier Kievit
Donders Institute for Brain, Cognition and Behavior, Radboud University Medical Center, Cognitive Neuroscience Department, Nijmegen, Netherlands

Aim During development, grey and white matter changes enable children to reach the maximum of their cognitive abilities. Researchers tend to specialize their research on one of these structures, thus it is still unclear if grey or white matter microstructure are playing distinct roles supporting cognitive development or if they are complementary. **Methods** To compare their role, we used structural equation models predicting cognitive performance with grey and white matter measures. Specifically, we compared morphometric grey matter measures (volume, cortical thickness and surface area) and indices of white matter microstructure (volume, fractional anisotropy and mean diffusivity). The models were tested in a large longitudinal cohort of adolescents (ABCD Study, N=11876) at 10 and 12 years old. We will also move beyond cross-sectional data and analyse the roles of grey and white matter changes in supporting cognitive development between 10 and 12 years old. **Results** We found that grey and white matter metrics bring partly different information to predict cognitive abilities. Indeed, the models with only grey or white matter explained respectively 22% and 19% of the variance in cognitive performance, but the model with both explained 32%. In particular, different metrics within grey and white matter had different predictive power and different regions for grey and white matter had the biggest impact on cognitive abilities. **Conclusion** These results show that studies focusing on a single metric in either grey or white matter to study the link between brain structure and cognitive development are missing a key part of the equation.

Background Diabetes is associated with a higher risk of dementia. Little is known on the underlying physiopathological process and some studies suggested that prediabetic stage has a deleterious effect on brain. Our aim was to determine the glucose metabolism disorders impact in mild cognitive impairment (MCI) subjects on cognitive functioning, Alzheimer's disease (AD) cerebrospinal fluid (CSF) and plasma biomarkers, and conversion to AD dementia. **Method** MCI participants of BALTAZAR study, a large-scale longitudinal multicenter cohort, were followed-up during 3 years. MCI participants were categorized based on their glucose metabolism status (non-diabetic, prediabetic, diabetic) at baseline. A committee of experts adjudicated MCI conversion to AD dementia. The association between glucose metabolism disorders and cognition, CSF and plasmatic AD biomarkers at baseline, and MCI conversion during the follow-up were determined using parametric tests and logistic regression. **Results** Of 400 MCI participants, 252 (63%) were non-diabetic, 80 (20%) prediabetics and 68 (17%) diabetics. At baseline, glucose metabolism disorders had no significant association with cognitive function. Prediabetics compared to diabetics had a significant lower plasma $A\beta_{1-42}$ concentration and a higher CSF P-tau/$A\beta_{1-42}$ ratio, and prediabetics compared to non-diabetics had a higher plasma $A\beta_{1-40}$ /$A\beta_{1-42}$ ratio. For 3 years of follow-up, 155 (31.2%) MCI converted to AD dementia. Prediabetes, but not diabetes, was associated with a two-fold risk of conversion to AD dementia (odds ratio (95% CI) = 2.02 (1.03-3.96)). **Conclusion** Prediabetes was an independent risk for dementia. Early detection and treatment of prediabetes in MCI patients could be critical for AD dementia prevention.

CONSCIOUSNESS, DEMENTIA AND CALCIUM CARBONATE: A NEW ETIOPATHOGENETIC THEORY

POSTER SESSION 07 - SECTION: AGING AND THE BRAIN

Angela Scibetta, Angela Scibetta
Family Doctor, Public Health, Ronchis (UD), Italy

Among all kinds of dementia, the senile dementia has still a multifactorial etiopathogenesis. What if we could find a calcium channel incrusted with a calcium salt molecule? What kind of damage could do at a local and adjacent cellular area? What if this formula could be the source of senile dementia? $CO_2 + H_2O \Leftrightarrow 2H^+ + CO_3^{2-} + Ca^{2+} >$ **$CaCO_3$** However, all these chemicals can be found in our interstitial fluid and neuronal membrane, according to the medical bibliography, I am expecting that: **Micro-regional level** Changes in the membrane next to the calcic channel Slight deformation of the adjacent protein sites Folding and production of beta amyloid protein Activation of the inflammatory process in order to repair the defect **Macro-regional level** Resting potential increase Spike transmission reduced Tao detachment from the axon Reduced consume of energy Reduced activity and local perfusion Water cortical concentration lowering Water falls by gravity into the ventricles Stoke risk increased and more compression next to ventricle As a result: Mechanical resistance would increase Membrane fluidity wouldn't change Pulsatility would decrease If we can demonstrate that the prefrontal and frontal area are involved in this process, we can explain the symptoms of dementia and the aging of the brain.

Background: Multiple mechanisms cause endothelial damage and vascular dysfunction, contributing to dementia. Endothelial cells can protect themselves from these insults by using coenzyme Q10 or its reduced form, ubiquinol. **Methods**: A total of 69 participants diagnosed with mild cognitive impairment (MCI) received either 200 mg/day ubiquinol (Ub) or placebo for 1 year. Cognitive assessment of patients was performed at baseline and after 1 year of follow-up. Doppler sonography, levels of Ubiquinol (Ub) and lipopolysaccharide (LPS) was examined. Cell viability and necrotic cell death were determined using the microvascular endothelial cell line bEnd3. **Results**: Coenzyme Q10 levels increased in patients supplemented for 1 year with ubiquinol versus the baseline group and the placebo group, these levels being higher in male than female patients. 21.2% of the ubiquinol group progressed to dementia, compared to 27.8% of the placebo group. This observation was reflected in an increase in the rate of breath retention, which was significant in male patients. Similarly, male patients after consuming ubiquinol showed lower lps levels compared to baseline. A significant negative correlation was established between plasma coenzyme Q10 concentration and necrosis-induced cell death in cultured bEnd3 cells when filtering for T2DM and hypertensive groups. **Conclusions**: Oral supplementation with ubiquinol increases plasma levels of coenzyme Q10 without side effects, reduces chronic inflammation and improves cerebral vasoreactivity and endothelial parameters in male patients. This suggests that ubiquinol supplementation might be recommended for patients with MCI as an adjunct to conventional treatment.

COMPARING THE ANTIDEPRESSANT-LIKE EFFICACY OF KETAMINE, CANNABIDIOL AND FLUOXETINE IN MALE AND FEMALE ADOLESCENT RATS

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Sandra Ledesma-Corvi[1], Elena Hernández-Hernández[2], M. Julia García-Fuster[1]

There is an urgent need for developing novel pharmacological treatment options for adolescent depression, and to ensure an optimal translational outcome to the clinic, sex should be included as a biological variable in preclinical studies. In this context, the present study compared the antidepressant-like potential of ketamine and cannabidiol, with the clinical standard fluoxetine, in adolescent rats exposed to maternal deprivation (as a model of early-life stress), while including a sex perspective. Moreover, changes in drug efficacy over time were evaluated by re-exposing rats to the same dose regimens during adulthood. Antidepressant-like responses were scored through a battery of distinctive tests (forced-swim, novelty suppressed-feeding, sucrose preference) across time. The main results proved an antidepressant-like potential for ketamine and cannabidiol in adolescent rats, although their efficacy was dependent on sex and prior stress exposure, as well as on treatment-length and the behavioral feature analyzed. In general, while all tested antidepressants in male rats improved certain affective-like features, female rats were mainly unresponsive to the treatments performed (except for certain benefits induced by ketamine), demonstrating the need for further characterizing proper treatments for this particular sex. Moreover, when rats were re-exposed in adulthood to the same drug regimens as in adolescence, a drop in efficacy was observed. These findings may have translational ramifications in that ketamine or cannabidiol could be moved forward as antidepressants for the adolescent depressed population, but not before further characterizing their potential long-term safety and/or beneficial vs. harmful effects for both sexes. Sex differences in the antidepressant-like potential of repeated electroconvulsive seizures in adolescent and adult rats: Regulation of the early stages of hippocampal neurogenesis.
Age and sex are critical factors for the diagnosis and treatment of major depression, since there is a well-known age-by-sex difference in the prevalence of major depression (being females the most vulnerable ones) and in antidepressant efficacy (being adolescence a less responsive period than adulthood). Although the induction of electroconvulsive seizures (ECS) is a very old technique in humans, there is not much evidence reporting sex- and age-specific aspects of this treatment. The present study evaluated the antidepressant- and neurogenic-like potential of repeated ECS across time in adolescent and adult rats (naïve or in a model of early life stress capable of mimicking a pro-depressive phenotype), while including a sex perspective. The main results demonstrated age- and sex-specific differences in the antidepressant-like potential of repeated ECS, since it worked when administered during adolescence or adulthood in male rats (although with a shorter length in adolescence), while in females rendered deleterious during adolescence and ineffective in adulthood. Yet, repeated ECS increased cell proliferation and vastly boosted young neuronal survival in a time-dependent manner for both sexes and independently of age. Moreover, pharmacological inhibition of basal cell proliferation prevented the antidepressant-like effect induced by repeated ECS in male rats, but only partially blocked the very robust increase in the initial cell markers of hippocampal neurogenesis. Overall, the present results suggest that the induction of the early phases of neurogenesis by ECS, besides having a role in mediating its antidepressant-like effect, might participate in some other neuroplastic actions, opening the path for future studies.

INVESTIGATING LONG-TERM EFFECTS OF PSYCHEDELIC DRUG DOI ON ANATOMICAL AND BEHAVIOURAL PLASTICITY IN A MOUSE MODEL

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Merima Sabanovic[1], Alberto Lazari[2], Thomas Akam[1], Vladyslav Vyazovskiy[3], David Bannerman[1], Jason Lerch[2], Mark Walton[1]
[1]University of Oxford, Experimental Psychology, Oxford, United Kingdom, [2]FMRIB Centre, Wellcome Centre for Integrative Neuroimaging, Nuffield Department Of Clinical Neurosciences, Oxford, United Kingdom, [3]University of Oxford, Department Of Physiology, Anatomy And Genetics, Oxford, United Kingdom

Psychedelics putatively aid fast and lasting remission from various neuropsychiatric disorders by heightening brain plasticity. Growing evidence in both humans and preclinical models shows increased cellular neuroplasticity in the days after psychedelic treatment. However, the link between these cellular effects and the profound shifts in behaviour remains unclear. We focus on the long-term (≤3-week-post-drug) effects of psychedelic drug DOI on the behavioural and whole-brain structural plasticity of C57BL/6 mice. Behavioural plasticity was tested as adaptability in a probabilistic two-step reversal-learning task, while structural plasticity was quantified via regional brain volume changes using *ex vivo* magnetic resonance imaging. We find an increase in regional grey matter volume of several sensory areas 24h after DOI administration, but preliminary results show these volume differences may not persist 3 weeks post-drug. In the reversal learning task, DOI-treated animals were quicker to adapt to learned reversals only in the first week post-drug but were later also quicker to adapt to a novel rule reversal when they started incorporating learning from reward omissions. However, overall choice accuracy remained comparable to control animals throughout the study. As psychedelic-enhanced plasticity is linked with increased environmental sensitivity, we additionally compared acute drug responses of animals injected in a novel versus familiar environment. Novelty enhanced animals' sensitivity to hallucination-like effects, while familiarity enhanced the animals' sensitivity to DOI's effects on exploration. Our results demonstrate that a single dose of DOI can trigger a complex timeline of enhanced higher-level plasticity changes in the weeks following psychedelic treatment, even in healthy animals.

Aim: About 10-30% of long-COVID patients, among multiple symptoms, suffer from persistent, debilitating cognitive deficits that alter their quality of life, and this independently from the severity of the initial infection. There is thus an urgent need to find an effective treatment for these patients. To date, no animal model recapitulates the neurocognitive symptoms of long-COVID. Our aim was therefore to define a rationale for the use of NX210c in long-COVID patients by correlating its properties with any neurological alterations which might cause cognitive impairments after SARS-CoV-2 infection. **Methods:** CNS-related effects of NX210c have been demonstrated during its preclinical and early clinical development, in particular on cognitive functions. The cerebral damages due to COVID-19 were picked up from the literature to describe how NX210c could tackle this emerging condition associated with cognitive deficits. **Results/Conclusions:** Our research with NX210c unravelled several targets and mechanisms that help restore cognition, enhance excitatory synaptic transmission, increase neuronal recovery after hypoxia, promote neuronal survival, alleviate neuroinflammation, stimulate remyelination, reduce blood-brain barrier permeability and even lower plasma homocysteine levels. Interestingly, all these processes can be impacted by SARS-CoV-2 infection. As NX210c combines these different properties into one single drug, it is expected to improve cognitive outcomes in long-COVID patients. A first-in-human study showed the good safety and tolerability profile of NX210c in healthy volunteers. The study design of a phase Ib/II clinical trial planned in 2022 to evaluate the safety, tolerability, pharmacokinetics, and efficacy of NX210c in patients with long COVID-related cognitive deficits will be presented.

THE EFFECT OF OXYTOCIN ON THE PERCEPTION OF TACTILE SENSATIONS OF INTERNAL AND EXTERNAL ORIGIN

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Yulong Huang[1], Lara Bardi[1], Chen Qu[2], Angela Sirigu[1]
[1]ISC CNRS UMR 5229, Disorders Of Brain, bron, France, [2]South China Normal University, Psychology, Guangzhou, China

Oxytocin (OT), is a neuropeptide hormone, well known for its impact on social cognition. Recent research in rodents has shown the role of oxytocin in the regulation of tactile sensations and social proximity through touch. In humans, the underlying mechanisms of how oxytocin modulates one's own and others' sensory perception remains unclear. Interestingly, skin contact experience is influenced by OT release *via* the vagus nerve, a pathway involved in interoceptive processing. In this study, we hypothesize that the role of OT in promoting social proximity may be mediated by a process in which internal sensory stimulation is reduced to bias individuals' attention to the social environment. We investigated the effects of 24 and 40IU intranasal oxytocin in a tactile stimulation task in 90 male participants before and after the administration. Subjects were asked to rate the effectiveness of the stimulation (tickly, intense, pleasant, irritating) delivered by a tickling device under self- or external-production conditions. Compared to externally produced stimulation, it is well known that we cannot tickle ourselves, because of the sensory effects anticipated by our brain. Hence, consistent with our hypothesis we primarily expected a decrease in tingling sensation during external stimulation due to the internal sensory attenuation effect of OT. Our results showed a significant effect of 24IU administration on reducing tactile sensation during pleasant ratings. We speculate that the effect of OT on bodily sensations could be the starting point for its broader social influence.

UPREGULATING ACETYLCHOLINE ENHANCES FORAGING OPTIMALITY

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Nikita Sidorenko[1], Hui-Kuan Chung[1], Boris Quednow[2], Alexander Jetter[3], Philippe Tobler[1]
[1]University of Zurich, Department Of Economics, Zurich Center For Neuroeconomics, Zurich, Switzerland, [2]University of Zurich, Experimental And Clinical Pharmacopsychology Department Of Psychiatry, Psychotherapy And Psychosomatics Psychiatric Hospital, Zurich, Switzerland, [3]University Hospital Zurich, Department Of Clinical Pharmacology And Toxicology, Zurich, Switzerland

Stick to the current course of action and exploit the rewards it provides or switch and explore other, potentially more rewarding options? In such foraging problems, options are experienced sequentially, and the agent needs to decide when to leave the current option for the next one. According to the Marginal Value Theorem (MVT), optimal foraging consists in leaving the current option when its reward rate falls below the average reward rate of all alternatives. However, foragers often violate this rule and exploit options longer than predicted by MVT. Here, we investigated whether upregulation of dopaminergic, noradrenergic, and cholinergic systems increases foraging optimality. We assessed this question with a double-blind, placebo-controlled design, where participants received placebo, a dopamine or norepinephrine reuptake inhibitor (methylphenidate or reboxetine), or the nicotinic acetylcholine receptor agonist nicotine. Randomly assigned to one of four medication groups, 160 healthy volunteers took the role of a foraging farmer who aims to optimize milk returns from cows in the fields. We found that on average our participants in all groups were biased towards overexploitation when foraging. Our results show that while methylphenidate and reboxetine administration had weak or no effects on this bias, nicotine significantly reduced deviation from foraging optimality, which resulted in better performance when compared to the placebo group. We also measured pupil dilation to investigate whether drug administration affects the role of arousal in solving the exploration-exploitation dilemma. Our findings will elucidate the neurochemical basis of decision optimality and speak to research on disorders affecting these functions.

Background: Endotoxin-induced neuroinflammation plays a crucial role in the pathogenesis and progression of various neurodegenerative diseases. A growing body of evidence supports that incretin-acting drugs possess various neuroprotective effects that can improve learning and memory impairments in Alzheimer's disease models. Thus, the present study aimed to investigate whether alogliptin, a dipeptidyl peptidase-4 inhibitor, has neuroprotective effects against lipopolysaccharide (LPS)-induced neuroinflammation and cognitive impairment in mice as well as the potential mechanisms underlying these effects.
Methods: Mice were treated with alogliptin (20 mg/kg/d; p.o.) for 14 days, starting 1 day prior to intracerebroventricular LPS injection (8 μg/μL in 3 μL).
Results: Alogliptin treatment alleviated LPS-induced cognitive impairment as assessed by Morris water maze and novel object
recognition tests. Moreover, alogliptin reversed LPS-induced increases in toll-like receptor 4 and myeloid differentiation primary response 88 protein expression, nuclear factor-κB p65 content, and microRNA-155 gene expression. It also rescued LPS-induced decreases in suppressor of cytokine signaling gene expression, cyclic adenosine monophosphate (cAMP) content,
and phosphorylated cAMP response element binding protein expression in the brain.
Conclusion: The present study sheds light on the potential neuroprotective effects of alogliptin against intracerebroventricular LPS-induced neuroinflammation and its associated memory impairment via inhibition of toll-like receptor 4/ myeloid differentiation primary response 88/ nuclear factor-κB signaling, modulation of microRNA-155/suppressor of cytokine signaling-1 expression, and enhancement of cAMP/phosphorylated cAMP response element binding protein signaling.

Adolescence is a neurodevelopmental critical period when the brain is especially susceptible to environmental factors. It is also a life stage where people tend to abuse drugs. Nicotine is the second most abused licit drug in the world. Among the illicit drugs, cannabis and its derivatives can be highlighted, including the recent rising epidemy of synthetic cannabinoids use. Most importantly, around 90% of cannabis users smoke tobacco, and 19% are considered nicotine dependent. However, short and long-term outcomes of this co-use by vulnerable populations (such as adolescents) are not clear. Thus, we investigated the consequences of heavy exposure to nicotine and a synthetic cannabinoid during adolescence. Male Swiss mice (PND28) were exposed to nicotine, WIN 55212-2 or both, for 20 days and evaluated in several behavioral tasks. Nicotine-exposed mice presented hyperlocomotion in the open field that was not affected by WIN co-exposure. Only mice that received nicotine and WIN showed a memory impairment in the novel object recognition task. These behavioral changes were not persistent since they were not detected when mice were evaluated in adulthood. Moreover, adult mice submitted to the same drug-exposure protocol starting at PND70 did not show any behavioral change. Investigation of drug receptors in the hippocampus showed a discreet reduction in β2-nicotine receptor subunit expression in all nicotine-exposed adolescents. In summary, we described an age-specific memory impairment induced by nicotine and WIN co-exposure in mice that is not persistent. Further studies are necessary to elucidate the mechanisms involved in this deficit. Funding: CNPq-Brazil, CAPES-Brazil, ISN.

FIVE-WEEK INTRANASAL NERVE GROWTH FACTOR TREATMENT IS SAFE AND FAVORS BRAIN NEUROGENESIS

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Nina Colitti, Franck Desmoulin, Alice Le Friec, Wafae Labriji, Lorenne Robert, Carla Cirillo, Isabelle Loubinoux
INSERM, Tonic, Toulouse, France

Objective: To date, no safe and effective pharmacological treatment has been clinically validated for improving post-stroke neurogenesis. Growth factors are good candidates but low safety has limited their application in the clinic. An additional restraint is the delivery route. Intranasal delivery (IN) presents many advantages. *Methods*: A brain lesion was induced in twenty-four rats. Nerve growth factor (NGF) 5 µg/kg/day or vehicle was given IN from day 10 post-lesion for two periods of five weeks, separated by a two-week wash out period with no treatment. Lesion volume and atrophy were identified by magnetic resonance imaging. Anxiety and sensorimotor recovery were measured by behavior tests. Neurogenesis, angiogenesis and inflammation were evaluated by histology at 3 months. *Results*: Remarkable neurogenesis occurred between the second and third month after the insult. Tissue reconstruction was clearly detected by T2 weighted MRI 3 months post-lesion and confirmed by histology. In the new tissue, NGF significantly increased the percentage of mature neo-neurons (19% *vs* 7%). Sensorimotor recovery was neither improved nor hampered by NGF during the first period of treatment. *Interpretation*. The first five-week period of treatment was very well tolerated and safe. The non-invasive NGF treatment can easily be transferred to the clinic. This study is the first presenting the effects of a long treatment with NGF and has shown an important tissue regeneration rate at 3 months. NGF increased neuron differentiation and survival. For the first time, we evidenced a MRI biomarker of neurogenesis and tissue reconstruction with T2 and diffusion weighted imaging.

KETAMINE DOES NOT PRODUCE CROSS-SENSITIZATION TO AMPHETAMINE-INDUCED LOCOMOTOR ACTIVITY IN MALE RATS

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Wei-Chung Hsu[1], Shuo-Fu Chen[1,2], Chuan-Yao Wang[2], Shu-Ting Wu[1], Ruey-Ming Liao[1,2]
[1]National Cheng Chi University, Psychology, Taipei City, Taiwan, [2]National Cheng Chi University, Institute Of Neuroscience, Taipei City, Taiwan

Aims: Repeated administration of psychostimulants produces an enduring and progressively enhanced behavioral response known as behavioral sensitization (BS), which has been implicated as a model of drug addiction. Ketamine is used to treat depression, but the issue of its abuse potential has been controversial. We adopted the cross-sensitization approach to investigate whether racemic ketamine (RS-KET) and one of its isomers (S)-ketamine (S-KET) could replace amphetamine to produce BS. Methods: Stimulant-induced BS on locomotor activity was tested by a pre- and a post-test with a lower dose of d-amphetamine (d-AMP; 0.5 mg/kg) conducted respectively before and after a 7-day intermittently repeated injections of 1 mg/kg d-AMP in male rats. RS-KET and S-KET (5 and 10 mg/kg) were separately tested in two groups of rats (n=14 each) during the cross-sensitization (CS) test. Further, the long-lasting effects of d-AMP-induced BS and KET-CS were examined following a 3-week duration of withdrawal. Results: The locomotor activity was significantly increased by d-AMP over the 7-day induction phase. Significant BS produced by d-AMP was verified by the hyperlocomotion induced by the challenging dose on the post-test. RS-KET and S-KET did not induce a CS in the d-AMP-sensitized rats. These results were replicated after a 3-week withdrawal. Conclusions: This study confirms BS of locomotor activity induced by d-AMP and shows that RS-KET or S-KET is insufficient to produce CS in the d-AMP-sensitized rats. Keywords: drug abuse, behavioral sensitization, cross-sensitization, ketamine isomers, psychostimulants

COMP360 PSILOCYBIN RESTORES REWARD LEARNING IMPAIRMENTS IN RATS CAUSED BY CHRONIC INTERFERON-ALPHA TREATMENT

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Justyna Hinchcliffe[1], Christopher Thomas[2], Caroline Golden[2], Aslihan Selimbeyoglu[2], Emma Robinson[1]
[1]Bristol University, Physiology, Pharmacology And Neuroscience, Bristol, United Kingdom, [2]Compass Pathways, Preclinical R&d, London, United Kingdom

Aims Impaired reward learning, an essential feature of affective disorders, can be recapitulated in mechanistically diverse animal models. For example, chronic inflammatory stimulation with interferon-alpha (IFNα) in rats disrupts performance in the Reward Learning Assay (RLA). We aimed to explore effects of COMP360 (COMPASS Pathways' proprietary psilocybin formulation) in IFNα-treated animals with this assay. **Methods** 48 male Lister-Hooded rats were divided into three groups (n=16); vehicle-vehicle (healthy control), IFNα-vehicle (disease phenotype control) and IFNα-COMP360 (experimental intervention). Vehicle or IFNα (100 units/kg, i.p.) was administered daily for two weeks before giving a single dose of vehicle or COMP360 (0.3 mg/kg, i.p.). Animals were tested in two RLAs with learning occurring before or after vehicle/COMP360 treatment, while daily vehicle/IFNα administration continued. In the RLA, rats dig for reward in a choice of digging substrates. Two substrates are consistently reward-paired during learning, one low value (single sucrose pellet), one high value (two pellets). Choice bias is quantified toward the high- vs. low-value substrate over 30 trials and group mean tested against zero bias with two-tailed one-sample t-test. **Results** Healthy control animals demonstrated significant choice bias for the high-value substrate ($p<0.001$), unlike disease phenotype controls ($p>0.05$). COMP360-treated animals showed some evidence of recovering high-value substrate choice bias 24 hours post-dose for previously learned substrates ($p=0.002$) and demonstrated high-value substrate choice bias in another RLA learned post-dose ($p=0.0002$). **Conclusion** The deleterious effects of chronic IFNα treatment on reward-driven choice bias in rats can be at least partially reversed by a single COMP360 dose (0.3 mg/kg).

TYPE 1 DIABETES MEDIATED MICROVASCULAR DYSFUNCTION AND IMPAIRED BEHAVIORAL PERFORMANCE IN MICE

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Sorabh Sharma, Kelly Tennant, Craig Brown
University of Victoria, Medical Sciences, Victoria, Canada

Introduction Recently our lab has shown that the brain capillaries routinely get clogged by cells and debris even under healthy conditions. The present study was undertaken to determine how type 1 diabetes mellitus (T1DM) affects this phenomenon, and whether obstructions contribute to cognitive decline. **Methods** C57BL/6 male and female mice were injected with streptozotocin to induce T1DM. These mice were implanted with cranial windows and cortical volumes were repeatedly imaged from 3-9 weeks after induction of diabetes. To model susceptibilities to short or long-lived obstructions, we injected (i.v.) 5µm diameter fluorescent microspheres in diabetic and control mice at 30 minutes and 3 days before euthanasia. To determine the impact of diabetes on cognitive activity, mice were subjected to a battery of behavioural tests. **Results** 2-photon imaging indicated that diabetic mice have higher rates of capillary stalling in somatosensory cortex that became more pronounced with duration of diabetes. We also observed significantly higher levels of short and long lived capillary obstructions in diabetic mice. Behaviourally, diabetic mice were not different from controls in tests of ambulatory activity. However, diabetic mice were significantly impaired in learning/memory tests such as the novel object recognition, water maze learning or reversal learning. **Conclusions** These studies suggests that diabetes is associated with greater risk for capillary obstructions in brain as well as learning/memory deficits. Our future aims will provide a mechanistic understanding of how diabetes elevates one's susceptibility to capillary obstructions and cognitive decline, and whether manipulating certain immune signalling pathways can alleviate these impairments.

Microvascular basis of cognitive impairment in type 1 diabetes.
The complex computations of the brain require a constant supply of blood flow to meet its immense metabolic needs. Perturbations in blood supply, even in the smallest vascular networks, can have a profound effect on neuronal function and cognition. Type 1 diabetes is a prevalent and insidious metabolic disorder that progressively and heterogeneously disrupts vascular signalling and function in the brain. As a result, it is associated with an array of adverse vascular changes such as impaired regulation of vascular tone, pathological neovascularization and vasoregression, capillary plugging and blood brain barrier disruption. In this review, we highlight the link between microvascular dysfunction and cognitive impairment that is commonly associated with type 1 diabetes, with the aim of synthesizing current knowledge in this field.

Aim: Selective serotonin reuptake inhibitors (SSRIs), the first line antidepressant treatment, have a variable efficacy. To explain such variability, we have demonstrated that SSRIs do not affect mood per se but amplify the influence of environment on mood. Since the environment is not only its objective features, but also the individual's experience of it, we hypothesized that the latter plays a key role in determining SSRI outcome. **Methods**: We tested CD-1 male mice reared either in a standard nest (SN) or a communal nest (CN) since they have different experiences of the environment as shown by their different adult neural and behavioural responses to the same challenges. CN consists in a single nest where three dams rear together their offspring and share caregiver behaviour from birth to weaning. At adulthood, both groups received either the SSRI fluoxetine (10 mg/kg/day) or vehicle for three weeks and behavioural responses, epigenetic changes and expression of the BDNF gene were assessed. **Results:** First, we confirmed previous studies showing that, at baseline, the two groups differently experience the same environmental challenges, CN displaying higher levels of offensive and anxiety-like behaviour and increased BDNF levels compared to SN mice. Furthermore, in line with our hypothesis, we showed that fluoxetine produced opposite effects on behaviour, BDNF levels and epigenetic regulation in CN and SN mice **Conclusions:** These findings show that fluoxetine effects depend on the individual experience of the environment, suggesting that subjective views potentially affect SSRI antidepressant outcome.

BEHAVIORAL SENSITIZATION OF LOCOMOTOR ACTIVITY INDUCED BY KETAMINE UNDER AN INTERMITTENTLY-REPEATED AND ESCALATING DOSE REGIMEN AND CROSS-SENSITIZATION TO D-AMPHETAMINE

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Ruey-Ming Liao[1,2], Wei-Chung Hsu[1], Shuo-Fu Chen[1], Chuan-Yao Wang[2], Shu-Ting Wu[1]
[1]National Cheng Chi University, Psychology, Taipei City, Taiwan, [2]National Cheng Chi University, Institute Of Neuroscience, Taipei City, Taiwan

Behavioral sensitization (BS) developed by repeated exposure to drugs of abuse causes a progressive and enduring enhancement of their psychomotor and positive reinforcing effects. While BS of the locomotor activity induced by d-amphetamine (d-AMP) has been widely reported in rats, the results reported to ketamine are mixed and controversial. This study was designed to test if BS would be developed to racemic ketamine (RS-KET) and one of its isomers (S)-ketamine (S-KET) given under an intermittently-repeated and escalating dose regimen. In male adult rats, KET-induced BS on locomotor activity was tested by a pre- and a post-test with a lower dose of 5 mg/kg conducted respectively before and after a 7-day intermittently-repeated injection regimen. During the induction phase, the doses of RS-KET or S-KET injection were 5 mg/kg for two days, 10 mg/kg for 3 days, and 15 mg/kg for two days. There was a 3-day withdrawal between the post-test session and the last day of aforementioned injection regimen. A subsequent test of cross-sensitization to d-AMP was conducted. The tests of BS to ketamine and cross-sensitization to d-AMP were re-conducted following a 3-week withdrawal. For the results, BS was significantly developed to either RS-KET or S-KET administered under the present regiment of intermittently-repeated and escalating dose injections, which was cross-sensitized to d-AMP. These pharmacological effects significantly remained after a 3-week withdrawal. Together with other reports, BS developed to KET is dependent on the injection regimen. BS to KET and d-AMP may be mediated by a common neurocircuitry.

DOES EARLY POSTNATAL METHAMPHETAMINE ADMINISTRATION ALONG WITH ALTERED ENVIRONMENT AFFECT NEUROTRANSMITTER AND OXIDATIVE STRESS LEVELS IN ADOLESCENCE OF LABORATORY RAT?

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Barbora Cechova[1], Jana Jurcovicova[1], Simon Vaculin[1], Stepan Sandera[1], Romana Slamberova[2]

Methamphetamine (MA), as massively abused psychoactive stimulant, has been associated with many neurological diseases. Chronic abuse of MA leads to significant changes in distribution and storage of brain neurotransmitters (NEUs), such as dopamine (DA), serotonin (5HT) and noradrenaline (NA) as well as glutamate (GLU). Adolescence is a transition period between childhood and adulthood. On postnatal days 1 -12, male rat pups by MA or saline (SA) as control group. During the pre-weaning or post-weaning period animals were exposed to different environments (standard cage or enriched environment (EE) cage). After weaning pups were housed single or grouped. At PD 28,35,45 rats were sacrificed, perfused and the striatum (STR) and hippocampus (HIP) were collected. Levels of NEUs and 4-hydroxynonenal (4HNE) were analyzed with ELISA kits. The effect of MA on levels of NEUs differed based on the housing environment as well as the age of animals. As a matter of oxidative stress, there is beneficial impact of enriched environment, but impairment induced by SA administration as a stressor. Thus, the present data demonstrate, that enriched environment and type of housing of animals may impact on NEU levels as well as oxidative stress in animals postnatally exposed to MA. Cortical plasticity is very active in early life at specific critical periods. This plasticity then progressively decreases into adulthood. While stabilizing cortical functions, reduced plasticity hampers recovery from developmental or congenital conditions such as amblyopia and cataract in adults. Recent studies suggest that a direct action on the cortical excitation/inhibition balance can help restore this plasticity by a direct or indirect action on GABAergic transmission. In this context, serotonin has been proposed to play a crucial role in the remodeling of cortical circuits. Here, we compare the behavioral scores of two adult rhesus macaques, in three behavioral tasks under systemic injections of Fluoxetine, a selective serotonin reuptake inhibitor, or control saline injections. We first measured perception thresholds on a simple manual detection task. We found that, under chronic Fluoxetine injections, the 50% correct detection luminance perceptual thresholds consistently decreased for both monkeys, at the same time that false alarm to noise independently increased. In a second study, we used a manual target detection task in the presence of distractors to probe decision-making under uncertainty. Using signal detection theory, we show that Fluoxetine decreases the decision threshold as observed in the previous task, but not the D-prime. Last, macaques performed a dual choice saccadic task. Targets were associated with different reward values based on their spatial location. These contingencies changed across days. Fluoxetine significantly reduced spatial and reward biases. Overall, this indicates that Fluoxetine has both an impact on low-level visual processes and on top-down control processes.

Aims Major depressive disorder is often associated with cognitive impairments, thus antidepressant treatments should target this domain in addition to the emotional one. Recently, the interplay between the brain and the immune system has been widely demonstrated, and compounds able to modulate immune function have been proposed as antidepressants. Here, we tested whether the administration of the antibiotic minocycline, with anti-inflammatory properties, improves the cognitive impairment associated with depression, since it has been proven to attenuate deficits in learning and memory in animal models of neurodegeneration. **Methods** C57BL6/J adult male mice were exposed to two weeks of chronic unpredictable mild stress to induce a depressive-like phenotype. At the end of the stress period, mice received either vehicle or minocycline for three weeks. We evaluated depressive-like profile, assessing anhedonia, and cognitive abilities through a place learning test. Finally, we investigated hippocampal functional plasticity measuring long-term potentiation (LTP). **Results** Chronic stress induced depressive-like behavior and cognitive impairment. Though the emotional dysregulation was recovered independently from treatment, cognitive performance was significantly enhanced only following minocycline administration. In particular, in the place learning test, when animals have to learn a new spatial configuration, minocycline-treated mice displayed a higher number of correct responses. Accordingly, the electrophysiological assessment showed that minocycline has recovered neuronal plasticity, minocycline-treated mice displaying higher LTP compared to vehicle. **Conclusions** These findings show that minocycline is effective in improving cognitive performances and enhancing neural plasticity in preclinical models, suggesting this drug as a potential treatment for cognitive impairments associated with depression.

Microglial-glucocorticoid receptor depletion alters the response of hippocampal microglia and neurons in a chronic unpredictable mild stress paradigm in female mice.
Chronic psychological stress is one of the most important triggers and environmental risk factors for neuropsychiatric disorders. Chronic stress can influence all organs via the secretion of stress hormones, including glucocorticoids by the adrenal glands, which coordinate the stress response across the body. In the brain, glucocorticoid receptors (GR) are expressed by various cell types including microglia, which are its resident immune cells regulating stress-induced inflammatory processes. To study the roles of microglial GR under normal homeostatic conditions and following chronic stress, we generated a mouse model in which the GR gene is depleted in microglia specifically at adulthood to prevent developmental confounds. We first confirmed that microglia were depleted in GR in our model in males and females among the cingulate cortex and the hippocampus, both stress-sensitive brain regions. Then, cohorts of microglial-GR depleted and wild-type (WT) adult female mice were housed for 3 weeks in a standard or stressful condition, using a chronic unpredictable mild stress (CUMS) paradigm. CUMS induced stress-related behavior in both microglial-GR depleted and WT animals as demonstrated by a decrease of both saccharine preference and progressive ratio breakpoint. Nevertheless, the hippocampal microglial and neural mechanisms underlying the adaptation to stress occurred differently between the two genotypes. Upon CUMS exposure, microglial morphology was altered in the WT controls, without any apparent effect in microglial-GR depleted mice. Furthermore, in the standard environment condition, GR depleted-microglia showed increased expression of pro-inflammatory genes, and genes involved in microglial homeostatic functions (such as Trem2, Cx3cr1 and Mertk). On the contrary, in CUMS condition, GR depleted-microglia showed reduced expression levels of pro-inflammatory genes and increased neuroprotective as well as anti-inflammatory genes compared to WT-microglia. Moreover, in microglial-GR

depleted mice, but not in WT mice, CUMS led to a significant reduction of CA1 long-term potentiation and paired-pulse ratio. Lastly, differences in adult hippocampal neurogenesis were observed between the genotypes during normal homeostatic conditions, with microglial-GR deficiency increasing the formation of newborn neurons in the dentate gyrus subgranular zone independently from stress exposure. Together, these findings indicate that, although the deletion of microglial GR did not prevent the animal's ability to respond to stress, it contributed to modulating hippocampal functions in both standard and stressful conditions, notably by shaping the microglial response to chronic stress.

Selecting antidepressants according to a drug-by-environment interaction: A comparison of fluoxetine and minocycline effects in mice living either in enriched or stressful conditions.
Selective serotonin reuptake inhibitors (SSRIs) are the first-line treatment for major depressive disorder. It has been recently proposed that these drugs, by enhancing neural plasticity, amplify the influences of the living conditions on mood. Consequently, SSRI outcome depends on the quality of the environment, improving symptomatology mainly in individuals living in favorable conditions. In adverse conditions, drugs with a different mechanism of action might have higher efficacy. The antibiotic minocycline, with neuroprotective and anti-inflammatory properties, has been recently proposed as a novel potential antidepressant treatment. To explore the drug-by-environment interaction, we compared the effects on depressive-like behavior and neural plasticity of the SSRI fluoxetine and minocycline in enriched and stressful conditions. We first exposed C57BL/6 adult female mice to 14 days of chronic unpredictable mild stress to induce a depressive-like profile. Afterward, mice received vehicle, fluoxetine, or minocycline for 21 days, while exposed to either enriched or stressful conditions. During the first five days, fluoxetine led to an improvement in enrichment but not in stress. By contrast, minocycline led to an improvement in both conditions. After 21 days, all groups showed a significant improvement in enrichment while fluoxetine worsened the depressive like behavior in stress. The effects of the drugs on neural plasticity, measured as long-term potentiation, were also environment-dependent. Overall, we show that the environment affects fluoxetine but not minocycline outcome, indicating that the latter represents a potential alternative to SSRIs to treat depressed patients living in adverse conditions. From a translation perspective, our finding call for considering the drug-by-environment interaction to select the most effective pharmacological treatment.

Brain-immune crosstalk in the treatment of major depressive disorder.
A growing number of studies are pointing out the need for a conceptual shift from a brain-centered to a body-inclusive approach in mental health research. In this perspective, the link between the immune and the nervous system, which are deeply interconnected and continuously interacting, is one of the most important novel theoretical framework to investigate the biological bases of major depressive disorder and, more in general, mental illness. Indeed, depressed patients show high levels of inflammatory markers, administration of pro-inflammatory drugs triggers a depressive symptomatology and antidepressant efficacy is reduced by excessive immune system activation. A number of molecular and cellular mechanisms have been hypothesized to act as a link between the immune and brain function, thus representing potential pharmacologically targetable processes for the development of novel and effective therapeutic strategies. These include the modulation of the kynurenine pathway, the crosstalk between metabolic and inflammatory processes, the imbalance in acquired immune responses, in particular T cell responses, and the interplay between neural plasticity and immune system activation. In the personalized medicine approach, the assessment and regulation of these processes have the potential to lead, respectively, to novel diagnostic approaches for the prediction of treatment outcome according to the patient's immunological profile, and to improved efficacy of antidepressant compounds through immune modulation.

Interplay between inflammation and neural plasticity: Both immune activation and suppression impair LTP and BDNF expression.
An increasing number of studies show that both inflammation and neural plasticity act as key players in the vulnerability and recovery from psychiatric disorders and neurodegenerative diseases. However, the interplay between these two players has been limitedly explored. In fact, while a few studies reported an immune activation, others conveyed an immune suppression, associated with an impairment in neural plasticity. Therefore, we hypothesized that deviations in inflammatory levels in both directions may impair neural plasticity. We tested this hypothesis experimentally, by acute treatment of C57BL/6 adult male mice with different doses of two inflammatory modulators: lipopolysaccharide (LPS), an endotoxin, and ibuprofen (IBU), a nonselective cyclooxygenase inhibitor, which are respectively a pro- and an anti-inflammatory agent. The results showed that LPS and IBU have different effects on behavior and inflammatory response. LPS treatment induced a reduction of body

temperature, a decrease of body weight and a reduced food and liquid intake. In addition, it led to increased levels of inflammatory markers expression, both in the total hippocampus and in isolated microglia cells, including Interleukin (IL)-1β, and enhanced the concentration of prostaglandin E (PGE). On the other hand, IBU increased the level of anti-inflammatory markers, decreased tryptophan 2,3-dioxygenase (TDO2), the first step in the kynurenine pathway known to be activated during inflammatory conditions, and PGE levels. Though LPS and IBU administration differently affected mediators related with pro- or anti-inflammatory responses, they produced overlapping effects on neural plasticity. Indeed, higher doses of both LPS and IBU induced a statistically significant decrease in the amplitude of long-term potentiation (LTP), in Brain-Derived Neurotrophic Factor (BDNF) expression levels and in the phosphorylation of the AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptor subunit GluR1, compared to the control group. Such effect appears to be dose-dependent since only the higher, but not the lower, dose of both compounds led to a plasticity impairment. Overall, the present findings indicate that acute treatment with pro- and anti-inflammatory agents impair neural plasticity in a dose dependent manner.

Combined Fluoxetine and Metformin Treatment Potentiates Antidepressant Efficacy Increasing IGF2 Expression in the Dorsal Hippocampus.
An increasing number of studies show that selective serotonin reuptake inhibitors (SSRIs) exert their therapeutic action, at least in part, by amplifying the influence of the living environment on mood. As a consequence, when administered in a favorable environment, SSRIs lead to a reduction of symptoms, but in stressful conditions, they show limited efficacy. Therefore, novel therapeutic approaches able to neutralize the influence of the stressful environment on treatment are needed. The aim of our study was to test whether, in a mouse model of depression, the combined administration of SSRI fluoxetine and metformin, a drug able to improve the metabolic profile, counteracts the limited efficacy of fluoxetine alone when administered in stressful conditions. Indeed, metabolic alterations are associated to both the onset of major depression and the antidepressant efficacy. To this goal, adult C57BL/6 male mice were exposed to stress for 6 weeks; the first two weeks was aimed at generating a mouse model of depression. During the remaining 4 weeks, mice received one of the following treatments: vehicle, fluoxetine, metformin, or a combination of fluoxetine and metformin. We measured liking- and wanting-type anhedonia as behavioral phenotypes of depression and assessed the expression levels of selected genes involved in major depressive disorder and antidepressant response in the dorsal and ventral hippocampus, which are differently involved in the depressive symptomatology. The combined treatment was more effective than fluoxetine alone in ameliorating the depressive phenotype after one week of treatment. This was associated to an increase in IGF2 mRNA expression and enhanced long-term potentiation, specifically in the dorsal hippocampus, at the end of treatment. Overall, the present results show that, when administered in stressful conditions, the combined fluoxetine and metformin treatment may represent a more effective approach than fluoxetine alone in a short term. Finally, our findings highlight the relevance of polypharmacological strategy as effective interventions to increase the efficacy of the antidepressant drugs currently available.

Predicting antidepressant treatment outcome based on socioeconomic status and citalopram dose.
Selective serotonin reuptake inhibitors (SSRIs), the most prescribed antidepressant drugs, have incomplete efficacy and no clear mechanism of action. In addition, no reliable methods to identify patients who will benefit from treatment is available. In this study, we show that citalopram, a commonly used SSRI, produces a dose-dependent amplification of the influence of the environment on mood, making the severity of symptoms dependent on the level of socioeconomic status (SES). As a consequence, based on SES, we were able to predict which patients would show remission following 12 weeks of treatment in the high, but not the low dose group. Our findings support a novel mechanism of action for SSRIs, which calls for a permissive rather than an instructive role of these drugs, and indicate that treatment outcome can be predicted based on SES and dose. Finally, our findings suggest that the patient's social and economic conditions should be considered in setting up personalized strategies aimed at enhancing SSRI efficacy.

Fluoxetine treatment affects the inflammatory response and microglial function according to the quality of the living environment.
It has been hypothesized that selective serotonin reuptake inhibitors (SSRIs), the most common treatment for major depression, affect mood through changes in immune function. However, the effects of SSRIs on inflammatory response are contradictory since these act either as anti- or pro-inflammatory drugs. Previous experimental and clinical studies showed that

the quality of the living environment moderates the outcome of antidepressant treatment. Therefore, we hypothesized that the interplay between SSRIs and the environment may, at least partially, explain the apparent incongruence regarding the effects of SSRI treatment on the inflammatory response. In order to investigate such interplay, we exposed C57BL/6 mice to chronic stress to induce a depression-like phenotype and, subsequently, to fluoxetine treatment or vehicle (21days) while being exposed to either an enriched or a stressful condition. At the end of treatment, we measured the expression levels of several anti- and pro-inflammatory cytokines and inflammatory mediators in the whole hippocampus and in isolated microglia. We also determined microglial density, distribution, and morphology to investigate their surveillance state. Results show that the effects of fluoxetine treatment on inflammation and microglial function, as compared to vehicle, were dependent on the quality of the living environment. In particular, fluoxetine administered in the enriched condition increased the expression of pro-inflammatory markers compared to vehicle, while treatment in a stressful condition produced anti-inflammatory effects. These findings provide new insights regarding the effects of SSRIs on inflammation, which may be crucial to devise pharmacological strategies aimed at enhancing antidepressant efficacy by means of controlling environmental conditions.

Fluoxetine effects on molecular, cellular and behavioral endophenotypes of depression are driven by the living environment.
Selective serotonin reuptake inhibitors (SSRIs) represent the most common treatment for major depression. However, their efficacy is variable and incomplete. In order to elucidate the cause of such incomplete efficacy, we explored the hypothesis positing that SSRIs may not affect mood per se but, by enhancing neural plasticity, render the individual more susceptible to the influence of the environment. Consequently, SSRI administration in a favorable environment promotes a reduction of symptoms, whereas in a stressful environment leads to a worse prognosis. To test such hypothesis, we exposed C57BL/6 mice to chronic stress in order to induce a depression-like phenotype and, subsequently, to fluoxetine treatment (21 days), while being exposed to either an enriched or a stressful condition. We measured the most commonly investigated molecular, cellular and behavioral endophenotypes of depression and SSRI outcome, including depression-like behavior, neurogenesis, brain-derived neurotrophic factor levels, hypothalamic-pituitary-adrenal axis activity and long-term potentiation. Results showed that, in line with our hypothesis, the endophenotypes investigated were affected by the treatment according to the quality of the living environment. In particular, mice treated with fluoxetine in an enriched condition overall improved their depression-like phenotype compared with controls, whereas those treated in a stressful condition showed a distinct worsening. Our findings suggest that the effects of SSRI on the depression- like phenotype is not determined by the drug per se but is induced by the drug and driven by the environment. These findings may be helpful to explain variable effects of SSRI found in clinical practice and to device strategies aimed at enhancing their efficacy by means of controlling environmental conditions.

Fractalkine receptor deficiency impairs microglial and neuronal responsiveness to chronic stress.
Chronic stress is one of the most relevant triggering factors for major depression. Microglial cells are highly sensitive to stress and, more generally, to environmental challenges. However, the role of these brain immune cells in mediating the effects of stress is still unclear. Fractalkine signaling - which comprises the chemokine CX3CL1, mainly expressed by neurons, and its receptor CX3CR1, almost exclusively present on microglia in the healthy brain - has been reported to critically regulate microglial activity. Here, we investigated whether interfering with microglial function by deleting the Cx3cr1 gene affects the brain's response to chronic stress. To this purpose, we housed Cx3cr1 knockout and wild-type adult mice in either control or stressful environments for 2weeks, and investigated the consequences on microglial phenotype and interactions with synapses, synaptic transmission, behavioral response and corticosterone levels. Our results show that hampering neuron-microglia communication via the CX3CR1-CX3CL1 pathway prevents the effects of chronic unpredictable stress on microglial function, short- and long-term neuronal plasticity and depressive-like behavior. Overall, the present findings suggest that microglia-regulated mechanisms may underlie the differential susceptibility to stress and consequently the vulnerability to diseases triggered by the experience of stressful events, such as major depression.
Brain Behav Immun, 2016; 55
23653679: Branchi I, Santarelli S, Capoccia S, Poggini S, D'Andrea I, Cirulli F, Alleva E
Antidepressant treatment outcome depends on the quality of the living environment: a pre-clinical investigation in mice.
Antidepressants represent the standard treatment for major depression. However, their efficacy is variable and incomplete. A growing number of studies suggest that the environment plays a major role in determining the efficacy of these drugs, specifically of selective serotonin reuptake inhibitors (SSRI). A recent hypothesis posits that the increase in serotonin levels induced by SSRI may not affect mood per se, but enhances neural plasticity and, consequently, renders the individual more

susceptible to the influence of the environment. Thus, SSRI administration in a favorable environment would lead to a reduction of symptoms, while in a stressful environment might lead to a worse prognosis. To test this hypothesis, we treated C57BL/6 adult male mice with chronic fluoxetine while exposing them to either (i) an enriched environment, after exposure to a chronic stress period aimed at inducing a depression-like phenotype, or (ii) a stressful environment. Anhedonia, brain BDNF and circulating corticosterone levels, considered endophenotypes of depression, were investigated. Mice treated with fluoxetine in an enriched condition improved their depression-like phenotype compared to controls, displaying higher saccharin preference, higher brain BDNF levels and reduced corticosterone levels. By contrast, when chronic fluoxetine administration occurred in a stressful condition, mice showed a more distinct worsening of the depression-like profile, displaying a faster decrease of saccharin preference, lower brain BDNF levels and increased corticosterone levels. Our findings suggest that the effect of SSRI on depression-like phenotypes in mice is not determined by the drug per se but is induced by the drug and driven by the environment. These findings may be helpful to explain variable effects of SSRI found in clinical practice and to device strategies aimed at enhancing their efficacy by means of controlling environmental conditions.

EFFECTS OF METHYLPHENIDATE ON BEHAVIORAL PATTERNS IN AN ANIMAL MODEL OF IMPULSIVE BEHAVIOR

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Juan Carlos Lopez, Antonio Pérez-Colorado, Nora Calle-Villa, Fatima Montiel, Estrella Diaz
University of Seville, Experimental Psychology, Sevilla, Spain

Goal and sign trackers animals show a different relationship with conditional stimulus (CS). For goal tracker (GT) animals, CS indicates the arrival of a reward, focusing the behavior toward the goal or approaching the place where the reward will be released. In contrast, sign tracker (ST) animals show a different behavior in the presence of CS, attributing to CS properties of US. This classification, despite being apparently simple, involves a correlation of different behavioral patterns, and this kind of response could be associated with possible risk factors linked to several mental illnesses, especially problems associated with attention and impulse control. Methylphenidate, a blocking dopamine and norepinephrine reuptake, is one of the most frequently used drugs to prevent these problems. Here, we analyzed the role of the dopamine receptors and methylphenidate in the different pattern of behavior in ST and GT animals. Training a cohort of rats in an autoshaping procedure, we studied how the methylphenidate administration modulates the symptoms of impulsivity. Results showed animals under drug effects only decreased motivational activity, but the ST phenotype was preserved. That is, the methylphenidate could be acting on the expression of the conditioned response, but not on the coding of incentive salience of stimuli. COGNITIVE CORRELATES AFTER LONG-TERM ADMINISTRATION OF METHYLPHENIDATE

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Juan Pedro Vargas, Manuel Portavella, Adela Batanero-Geraldo, Esperanza Quintero, Reyes Martínez
Universidad de Sevilla, Psicología Experimental, Sevilla, Spain

The purpose of the present study was to analyze the effect of chronic consumption of methylphenidate during adolescence on the maturational process of the prefrontal cortex in an animal model of hyperactivity. Adolescent animals (35d) were treated with methylphenidate for a period of 20 days and behaviorally tested during adulthood (98d). Rats were phenotyped using an autoshaping procedure prior to pharmacological treatment and prior to behavioral testing. The results showed that animals treated with methylphenidate during adolescence show deficiencies in sustained attention tasks, but not in information filtering tasks. These effects were produced in the high-dose group and the effect was more intense in males than in females. Furthermore, pharmacological treatment affected animals differently depending on their phenotype (goal-tracker vs sign-tracker). These results suggest that chronic consumption of methylphenidate, at least in high doses, could cause neurodevelopmental alterations and that these alterations are not homogeneous but depend on individual characteristics.

EFFECTS OF GLUTAMATERGIC MODULATION ON DIFFERENT TYPES OF IMPULSIVITY IN SPRAGUE-DAWLEY RATS

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Jovana Aranđelović[1], Vladimir Stevanović[1], Bojan Batinić[2], Vanja Todorović[3], Anja Santrač[1], Kristina Mirković[1], Aleksa Jovanović[1], Jana Kojić[1], Tamara Major[1], Miroslav Savić[1]

Aims: Impulsive disorders could be present in many psychiatric disorders in which the glutamatergic neurotransmission is affected. We aimed to assess the relationship between impulsivity parameters and types of impulsivity that could be influenced by the NMDA antagonist MK-801. Methodology: Two-month-old male Sprague-Dawley rats were trained in the variable delay-to-signal protocol modified for touchscreen with a fixed intertrial interval (ITI, 6s). Prior to testing, animals were treated i.p. with MK-801 (experiment 1: 0.03mg/kg or 0.05mg/kg, experiment 2: 0.05mg/kg or 0.2mg/kg) or with saline. Premature response rate (PR) during testing was analyzed in the first 20 trials with ITI 6s (PR4si and PR6si, motor impulsivity), next 60 trials with randomly distributed ITI of 9s or 15s (PR9s and PR15s, respectively) (temporal impulsivity) and then in the last 20 trials with ITI 6s again (PR6sf, reflective impulsivity). In a separate experiment, dependance between PRs across test stages was estimated with principal component analysis (PCA) applied to 61 control animals. Results: PCA revealed that PRs were independent from each another, except for PR4si and PR6si. Animals treated with MK-801 0.05mg/kg showed higher PR9s, PR15s and PR6sf, while 0.2mg/kg decreased PR4s compared to controls. Conclusion: Motor impulsivity measured by PR4si was decreased by the higher dose of MK-801 tested, possibly due to the observed repetitive exploration of chamber. MK-801 administered at 0.05mg/kg affected cognitive impulsivity, by inducing delay intolerance measured through PR9s and PR15s, which could be interpreted as temporal impulsivity, but also by increasing PR6sf, as a proposed parameter related to reflective impulsivity.

Positive and Negative Selective Allosteric Modulators of α5 GABAA Receptors: Effects on Emotionality, Motivation, and Motor Function in the 5xFAD Model of Alzheimer's Disease.
Positive and negative allosteric modulators of α5 GABAA receptors (PAM and NAM, respectively) are worthy of investigation as putative treatments of Alzheimer's disease (AD). However, their potential to modify a dynamic range of behaviors in AD models needs to be systematically examined.

Curcumin Loaded PEGylated Nanoemulsions Designed for Maintained Antioxidant Effects and Improved Bioavailability: A Pilot Study on Rats.
The current study describes the experimental design guided development of PEGylated nanoemulsions as parenteral delivery systems for curcumin, a powerful antioxidant, as well as the evaluation of their physicochemical characteristics and antioxidant activity during the two years of storage. Experimental design setup helped development of nanoemulsion templates with critical quality attributes in line with parenteral application route. Curcumin-loaded nanoemulsions showed mean droplet size about 105 nm, polydispersity index <0.15, zeta potential of -40 mV, and acceptable osmolality of about 550 mOsm/kg. After two years of storage at room temperature, all formulations remained stable. Moreover, antioxidant activity remained intact, as demonstrated by DPPH (IC50 values 0.078-0.075 mg/mL after two years) and FRAPS assays. In vitro release testing proved that PEGylated phospholipids slowed down the curcumin release from nanoemulsions. The nanoemulsion carrier has been proven safe by the MTT test conducted with MRC-5 cell line, and effective on LS cell line. Results from the pharmacokinetic pilot study implied the PEGylated nanoemulsions improved plasma residence of curcumin 20 min after intravenous administration, compared to the non-PEGylated nanoemulsion (two-fold higher) or curcumin solution

(three-fold higher). Overall, conclusion suggests that developed PEGylated nanoemulsions present an acceptable delivery system for parenteral administration of curcumin, being effective in preserving its stability and antioxidant capacity at the level highly comparable to the initial findings.

Positive modulation of α5GABAA receptors leads to dichotomous effects in rats on memory pattern and GABRA5 expression in prefrontal cortex and hippocampus.
Positive allosteric modulators (PAMs) of α5GABA receptors (α5GABAARs) are emerging as potential therapeutics for a range of neuropsychiatric disorders. However, their role in memory processing of healthy animals is not sufficiently examined. We tested the effects of MP-III-022 (1 mg/kg, 2.5 mg/kg and 10 mg/kg), a PAM known to be selective for α5GABAARs and devoid of prominent side-effects, in different behavioral paradigms (Morris water maze, novel object recognition test and social novelty discrimination) and on GABRA5 expression in Wistar rats, 30 min and 24 h after intraperitoneal treatment administration. The lowest dose tested worsened short-term object memory. The same dose, administered two times in a span of 24 h, improved spatial and impaired object and, at a trend level, social memory. The highest dose had a detrimental effect on all types of long-term memory (object memory at a trend level) and short-term spatial memory, but improved short-term object and social memory. Distinct sets of expression changes were detected in both prefrontal cortex and two regions of the hippocampus, but the latter ones could be assessed as more consequential. An increase of GABRA5 mRNA in CA2 occurred in parallel with improvement of object and social, but impairment of spatial memory, while the opposite happened with a trend level change in CA1. Our study demonstrates the variability of the roles of the α5GABAAR based on its level of expression and localization, in dependence on the type and protocol of cognitive tasks, as well as the respective timing of pharmacological modulation and testing.

AC253, a novel amylin receptor antagonist, neutralizes the depressant effects of amyloid-β peptide (Aβ) and human amylin on hippocampal long-term potentiation (LTP) in mice brain slice experimentation (Kimura et.al. J Neurosci 2012). These our results show that the effects of Aβ and amylin on LTP are expressed via the amylin receptor, and blockade of this receptor by AC253 increases LTP even in transgenic mice overexpressing Aβ (5XFAD). In this study, our purpose is to elucidate whether acute care of AC253 improves cognitive deficits in a model mouse of Alzheimer's disease (AD). In order to accurate delivery of these peptide quickly, we administered directly into the brain stem. By that means, we adopted a bent needle with special angle for intracisternal (i.cist.) injection into conscious mice (Ueda at.el. EUR J PHARMACOL 1979). To determine whether the peptide affects cognitive function, we performed Y-maze Spontaneous Alternation test and Fear Conditioning test. First, we investigate that 0.01 ml Aβ (1 mM) administration in mice. Both tests showed dramatically reduced levels of performance as compared with 0.01 ml PBS administration as a control. Furthermore, another i.cist. administration of AC253 (5 mM) at 30 min before Aβ administration recovered from the depressant effects on spontaneous performance in the both teats. Our next step should be to examine whether depressed levels of spontaneous alternation performance on the behavioral test observed in 5XFAD, could be restored with AC253. Then we show that human Amylin receptor antagonists serve as potentially useful therapeutic agents in severe level of AD.

Background: Antidepressants (ADs) are the basis for the treatment of major depression. Although increasingly safer, ADs remain only partially adequate as individual patient response variability and treatment outcome are highly unpredictable. Systematic studies are warranted to model and understand variability within and across treatments. **Objective:** To model inter-individual behavioral biomarkers of outcome using two different ADs. **Methodology:** The Unpredictable Chronic Mild Stress (UCMS) paradigm is used to induce (4 weeks) and to maintain (3 additional weeks) a depressive-like phenotype. Mice are exposed to 3 mild stressors daily in a randomized way. Depressive- and anxiety-like behavior, and memory evaluations are performed longitudinally. Animals with full blown depressive-like phenotype are subjected to a reversal protocol with fluoxetine (10mg/kg) or desipramine (10mg/kg) given over 3 weeks. **Results:** The UCMS successfully establishes depressive-like phenotype in about 90% of animals, confirmed by behavioral evaluations (Tail Suspension Test (TST), Fur coat (FC), Splash Test (ST), Anhedonia, Elevated-Plus maze (EPM), Novel object recognition test (NORT), and Weight Gain (WG)) and the post-hoc analysis of the Z-Score obtained from the mean of behavioral tests. Behavioral analysis at the end of protocol suggests that the depressive phenotype is maintained throughout the reversal protocol in saline-treated mice and that fluoxetine and desipramine partially reverse it. Post-hoc analysis allows to distinguish subpopulations of responders and non-responders. **Conclusions:** This design successfully models interindividual variability to AD treatment distinguishing between responders and non-responders. The outcome is comparable between fluoxetine and desipramine. Alternative analyses are considered. **Acknowledgements**: ERA-NET NEURON-040 (ANTaRES), Mineco-FPU fellowship, IRESP, ANR-19-CE37-0017.

Immunotherapies (PD-1/PD-L1) are promising approaches to treat cancer patients, but neurological consequences have been described. However, no objective neuropsychological evaluation of cognitive decline has yet been conducted. Here, we studied the impact of cancer and immunotherapy on emotional reactivity, cognitive functions, and underlying mechanisms as humoral immune cells cerebral entry or nervous pathways. C57Bl/6j mice were unilaterally injected in the flank with highly immunogenic colon cancer cells (MC38), less immunogenic melanoma cells (B16F10/B16F10-Ova) or corresponding lysates, to first define impact of cancer-related inflammatory environment on mice behavior. In a second set of experiments, anti-PD1 or control IgG was injected twice from D3 (B16F10) and D5 (MC38) post-tumor transplantation. Based on tumor growth kinetics, we assessed cognitive performance and emotional reactivity using a battery of behavioral tests. B16F10 mice showed impaired short-term memory, while F10-Ova and MC38 mice or receiving the corresponding lysate were prone to more pronounced cognitive deficit, with symptoms of anxiety and resignation. After PD-1 treatment, tumor growth was delayed, but cognitive impairment and resignation were exacerbated compared to cancer alone, only in MC38 mice. In brain slices, infiltration of macrophages (MHCII, CD206) within the circumventricular organs and over-expression of the indoleamine 2,3-dioxygenase (IDO) in the mesencephalic trigeminal nucleus and tract were highlighted in MC38 and F10-Ova mice. Our data indicate that immunotherapy, by delaying tumor growth, improves emotional disorders but worsens cognitive dysfunctions depending on cancer immunogenicity. The study of underlying mechanisms will guide the search for key targets actionable to maintain cancer patient quality of life.

PREDICTIVE AND CONSTRUCT VALIDITY IN A MOUSE MODEL OF CHEMOTHERAPY-INDUCED COGNITIVE IMPAIRMENT

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Victoria Aurora Ossorio-Salazar, Zsuzsanna Callaerts-Vegh, Rudi D'Hooge
KU Leuven, Biological Psychology, Leuven, Belgium

The quality of life in cancer survivors is often affected by the (long-term) side-effects of chemotherapy. The condition is known as chemotherapy-induced cognitive impairment (CICI), and affects executive functions, information-processing speed, attention, learning and memory. CICI has been related to leukoencephalopathy (white matter damage). At present, there are no approved evidence-based interventions to prevent CICI or its underlying leukoencephalopathy. Animal models with predictive and construct validity are generally thought be instrumental to the preclinical development of such interventions *(Crawley, 2007)*. Therefore, we examined the long-term (adult) consequences of triple systemic injections of the chemotherapeutic **methotrexate** (MTX) in juvenile mice, which putatively models CICI in children treated for acute lymphoblastic leukemia *(Gibson et al., Cell 2019).* We also investigate the attenuating effects of miconazole, an antifungal agent with remyelination properties. Juvenile C57BL/6 mice were injected with MTX (or saline) on postnatal days 21, 28, and 35, followed by miconazole (one daily injection of from postnatal day 36 through 42). During adulthood, subjects were tested on a behavioral battery that assesses aspects of cognition, social behavior and emotional reactivity. Immunohistochemical analyses inspected myelin basic protein expression, a biomarker of white matter integrity. Predictive and construct validity requires the CICI model to reproduce MTX-induced behavioral impairment, but also adjuvant miconazole administration alleviate myelin damage induced by MTX exposure.

OPPOSING EFFECTS OF POSTNATAL AND JUVENILE FLUOXETINE TREATMENT ON EMOTIONAL BEHAVIOUR, PROTEIN TRANSLATION, AND BIOENERGETICS.

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Utkarsha Ghai[1], Sashaina Fanibunda[2], Parul Chachra[1], Ambalika Sarkar[1], Megha Maheshawari[1], Vivek Singh[1], Vidita Vaidya[3]

Prior evidence indicates that treatment with selective serotonin reuptake inhibitors (SSRI) may evoke distinct changes in mood-related behavior depending on the temporal window of drug administration. We focused on two early time windows, namely: Postnatal and Juvenile windows. Postnatal Fluoxetine (PNFlx) evoked long-lasting increases in anxiety- and despair-like behavior, whereas Juvenile Fluoxetine (JFlx) elicited persistent decreases in anxiety- and despair-like behavior. The starkly differing behavioral outcomes were accompanied by differential global transcriptome changes in the mPFC, with minimal overlap in gene regulation. Further, the mTOR signaling pathway was differentially regulated in PNFlx versus JFlx animals. Opposing patterns of proteins involved in mitochondrial biogenesis and function were observed, with a decline in the mPFC of PNFlx animals in contrast to the increase following JFlx treatment. We found contrasting effects in ATP levels and OxPhos efficiency in PNFlx versus JFlx treatment. We observed a significant increase in mitochondrial function in PNFlx animals treated with NAM, reversing the mitochondrial decline and the pro-depressive effects observed with PNFlx. We show that SSRI treatment in postnatal versus juvenile windows evokes opposing effects on anxiety- and despair-like behavior, along with a differential and minimal overlap of the mPFC transcriptome, differential regulation of the mTOR pathway accompanied with opposing changes in the bioenergetics. We further establish a causal link between bioenergetics and despair-like behavior by reversing the pro-depressive effects of PNFlx using NAM treatment. Our findings highlight two distinct windows of early life in which SSRI exposure evokes starkly differing effects on behavior, gene regulation, and bioenergetics.

Serotonin regulates mitochondrial biogenesis and function in rodent cortical neurons via the 5-HT receptor and SIRT1-PGC-1α axis.
Mitochondria in neurons, in addition to their primary role in bioenergetics, also contribute to specialized functions, including regulation of synaptic transmission, Ca homeostasis, neuronal excitability, and stress adaptation. However, the factors that influence mitochondrial biogenesis and function in neurons remain poorly elucidated. Here, we identify an important role for serotonin (5-HT) as a regulator of mitochondrial biogenesis and function in rodent cortical neurons, via a 5-HT receptor-mediated recruitment of the SIRT1-PGC-1α axis, which is relevant to the neuroprotective action of 5-HT. We found that 5-HT increased mitochondrial biogenesis, reflected through enhanced mtDNA levels, mitotracker staining, and expression of mitochondrial components. This resulted in higher mitochondrial respiratory capacity, oxidative phosphorylation (OXPHOS) efficiency, and a consequential increase in cellular ATP levels. Mechanistically, the effects of 5-HT were mediated via the 5-HT receptor and master modulators of mitochondrial biogenesis, SIRT1 and PGC-1α. SIRT1 was required to mediate the effects of 5-HT on mitochondrial biogenesis and function in cortical neurons. In vivo studies revealed that 5-HT receptor stimulation increased cortical mtDNA and ATP levels in a SIRT1-dependent manner. Direct infusion of 5-HT into the neocortex and chemogenetic activation of 5-HT neurons also resulted in enhanced mitochondrial biogenesis and function in vivo. In cortical neurons, 5-HT enhanced expression of antioxidant enzymes, decreased cellular reactive oxygen species, and exhibited neuroprotection against excitotoxic and oxidative stress, an effect that required SIRT1. These findings identify 5-HT as an upstream regulator of mitochondrial biogenesis and function in cortical neurons and implicate the mitochondrial effects of 5-HT in its neuroprotective action.

The Hallucinogenic Serotonin Receptor Agonist, 2,5-Dimethoxy-4-Iodoamphetamine, Promotes cAMP Response Element Binding Protein-Dependent Gene Expression of Specific Plasticity-Associated Genes in the Rodent Neocortex.
Psychedelic compounds that target the 5-HT receptor are reported to evoke psychoplastogenic effects, including enhanced dendritic arborization and synaptogenesis. Transcriptional regulation of neuronal plasticity-associated genes is implicated in the cytoarchitectural effects of serotonergic psychedelics, however, the transcription factors that drive this regulation are poorly elucidated. Here, we addressed the contribution of the transcription factor cyclic adenosine monophosphate (cAMP)-response element binding protein (CREB) in the regulation of neuronal plasticity-associated genes by the hallucinogenic 5-HT receptor agonist, 2,5-dimethoxy-4-iodoamphetamine (DOI). studies with rat cortical neurons indicated that DOI enhances the phosphorylation of CREB (pCREB) through mitogen-activated protein (MAP) kinase and calcium/calmodulin dependent kinase II (CaMKII) pathways, with both cascades contributing to the DOI-evoked upregulation of , and expression, whilst the upregulation of and mRNA involved the MAP kinase and CaMKII pathway respectively. We observed a robust DOI-evoked increase in the expression of several neuronal plasticity-associated genes in the rat neocortex . This DOI-evoked upregulation of neuronal plasticity-associated genes was completely blocked by the 5-HT receptor antagonist MDL100,907 and was also abrogated in the neocortex of 5-HT receptor deficient mice. Further, 5-HT receptor stimulation enhanced pCREB enrichment at putative cAMP response element (CRE) binding sites in the , , , , but not and , promoters in the rodent neocortex. The DOI-mediated transcriptional induction of , and was significantly attenuated in the neocortex of CREB deficient/knockout (CREBαδ KO) mice. Collectively, these results indicate that the hallucinogenic 5-HT receptor agonist DOI leads to a rapid transcriptional upregulation of several neuronal plasticity-associated genes, with a subset of them exhibiting a CREB-dependent regulation. Our findings raise the intriguing possibility that similar to slow-acting classical antidepressants, rapid-action serotonergic psychedelics that target the 5-HT receptor may also recruit the transcription factor CREB to enhance the expression of neuronal plasticity-associated genes in the neocortex, which could in turn contribute to the rapid psychoplastogenic changes evoked by these compounds.

Postnatal Fluoxetine Treatment Alters Perineuronal Net Formation and Maintenance in the Hippocampus.
Elevation of serotonin via postnatal fluoxetine (PNFlx) treatment during critical temporal windows is hypothesized to perturb the development of limbic circuits thus establishing a substratum for persistent disruption of mood-related behavior. We examined the impact of PNFlx treatment on the formation and maintenance of perineuronal nets (PNNs), extracellular matrix (ECM) structures that deposit primarily around inhibitory interneurons, and mark the closure of critical period plasticity. PNFlx treatment evoked a significant decline in PNN number, with a robust reduction in PNNs deposited around parvalbumin (PV) interneurons, within the CA1 and CA3 hippocampal subfields at postnatal day (P)21 in Sprague Dawley rat pups. While the reduction in CA1 subfield PNN number was still observed in adulthood, we observed no change in colocalization of PV-positive interneurons with PNNs in the hippocampi of adult PNFlx animals. PNFlx treatment did not alter hippocampal PV, calretinin (CalR), or Reelin-positive neuron numbers in PNFlx animals at P21 or in adulthood. We did observe a small, but significant increase in somatostatin (SST)-positive interneurons in the DG subfield of PNFlx-treated animals in adulthood. This was accompanied by altered GABA-A receptor subunit composition, increased dendritic complexity of apical dendrites of CA1 pyramidal neurons, and enhanced neuronal activation revealed by increased c-Fos-positive cell numbers within hippocampi of PNFlx-treated animals in adulthood. These results indicate that PNFlx treatment alters the formation of PNNs within the hippocampus, raising the possibility of a disruption of excitation-inhibition (E/I) balance within this key limbic brain region.

THE INTERACTION BETWEEN ANTIDEPRESSANTS AND ENVIRONMENT DETERMINES TREATMENT OUTCOME IN A PRECLINICAL MODEL OF ADOLESCENCE-ONSET DEPRESSION

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Naomi Ciano Albanese[1,2], Caterina Barezzi[1], Claudia Delli Colli[1,3], Silvia Poggini[1], Igor Branchi[1]
[1]Istituto Superiore di Sanità, Center For Behavioral Science And Mental Health, Roma, Italy, [2]Sapienza University of Rome, Phd Program In Neurosciences, Roma, Italy, [3]Sapienza University of Rome, Pharmacology And Toxicology Pharmacology "vittorio Erspamer", Rome, Italy

Aims Adolescence-onset depression leads to more severe clinical symptoms, a longer duration of illness, and a higher rate of suicidality in adulthood. The first-line treatment for depression is selective serotonin reuptake inhibitors (SSRIs), but their efficacy is incomplete. Recently, it has been proposed that SSRIs do not affect mood per se, but, by enhancing neural plasticity, amplify the influences of the living environment on mood. Therefore, we hypothesized that treatment with antidepressants for adolescence-onset depression has to be administered in a supportive environment to have the highest efficacy. **Methods** We exposed C57BL/6 male mice from weaning to adulthood either in social conditions or social isolation to induce a depressive-like phenotype. In adulthood, socially housed mice have been exposed to the enriched environment and received vehicle. Isolated subjects were assigned to four groups: exposed to standard or enriched environment while receiving fluoxetine or vehicle. We assessed the efficacy of fluoxetine, enrichment, or their combination to treat the depressive-like phenotype in the elevated plus-maze, forced swim, and open field test. **Results** Adolescent isolation induced both depressive- and anxiety-like behavior. Environmental enrichment, but not fluoxetine alone, counterbalanced the detrimental effects of isolation, as indicated by the normalization of floating behavior in the forced swim test, locomotor activity in the open field, and time spent in the open arms in the elevated plus-maze. It is worth noting that fluoxetine effects were determined by the environment. **Conclusions** These findings suggest that the environment is key in treating depression and SSRI treatment can potentiate its impact.

Selecting antidepressants according to a drug-by-environment interaction: A comparison of fluoxetine and minocycline effects in mice living either in enriched or stressful conditions.
Selective serotonin reuptake inhibitors (SSRIs) are the first-line treatment for major depressive disorder. It has been recently proposed that these drugs, by enhancing neural plasticity, amplify the influences of the living conditions on mood. Consequently, SSRI outcome depends on the quality of the environment, improving symptomatology mainly in individuals living in favorable conditions. In adverse conditions, drugs with a different mechanism of action might have higher efficacy. The antibiotic minocycline, with neuroprotective and anti-inflammatory properties, has been recently proposed as a novel potential antidepressant treatment. To explore the drug-by-environment interaction, we compared the effects on depressive-like behavior and neural plasticity of the SSRI fluoxetine and minocycline in enriched and stressful conditions. We first exposed C57BL/6 adult female mice to 14 days of chronic unpredictable mild stress to induce a depressive-like profile. Afterward, mice received vehicle, fluoxetine, or minocycline for 21 days, while exposed to either enriched or stressful conditions. During the first five days, fluoxetine led to an improvement in enrichment but not in stress. By contrast, minocycline led to an improvement in both conditions. After 21 days, all groups showed a significant improvement in enrichment while fluoxetine worsened the depressive like behavior in stress. The effects of the drugs on neural plasticity, measured as long-term potentiation, were also environment-dependent. Overall, we show that the environment affects fluoxetine but not minocycline outcome, indicating that the latter represents a potential alternative to SSRIs to treat depressed patients living in adverse conditions. From a translation perspective, our finding call for considering the drug-by-environment interaction to select the most effective pharmacological treatment.

Microglial-glucocorticoid receptor depletion alters the response of hippocampal microglia and neurons in a chronic

unpredictable mild stress paradigm in female mice.
Chronic psychological stress is one of the most important triggers and environmental risk factors for neuropsychiatric disorders. Chronic stress can influence all organs via the secretion of stress hormones, including glucocorticoids by the adrenal glands, which coordinate the stress response across the body. In the brain, glucocorticoid receptors (GR) are expressed by various cell types including microglia, which are its resident immune cells regulating stress-induced inflammatory processes. To study the roles of microglial GR under normal homeostatic conditions and following chronic stress, we generated a mouse model in which the GR gene is depleted in microglia specifically at adulthood to prevent developmental confounds. We first confirmed that microglia were depleted in GR in our model in males and females among the cingulate cortex and the hippocampus, both stress-sensitive brain regions. Then, cohorts of microglial-GR depleted and wild-type (WT) adult female mice were housed for 3 weeks in a standard or stressful condition, using a chronic unpredictable mild stress (CUMS) paradigm. CUMS induced stress-related behavior in both microglial-GR depleted and WT animals as demonstrated by a decrease of both saccharine preference and progressive ratio breakpoint. Nevertheless, the hippocampal microglial and neural mechanisms underlying the adaptation to stress occurred differently between the two genotypes. Upon CUMS exposure, microglial morphology was altered in the WT controls, without any apparent effect in microglial-GR depleted mice. Furthermore, in the standard environment condition, GR depleted-microglia showed increased expression of pro-inflammatory genes, and genes involved in microglial homeostatic functions (such as Trem2, Cx3cr1 and Mertk). On the contrary, in CUMS condition, GR depleted-microglia showed reduced expression levels of pro-inflammatory genes and increased neuroprotective as well as anti-inflammatory genes compared to WT-microglia. Moreover, in microglial-GR depleted mice, but not in WT mice, CUMS led to a significant reduction of CA1 long-term potentiation and paired-pulse ratio. Lastly, differences in adult hippocampal neurogenesis were observed between the genotypes during normal homeostatic conditions, with microglial-GR deficiency increasing the formation of newborn neurons in the dentate gyrus subgranular zone independently from stress exposure. Together, these findings indicate that, although the deletion of microglial GR did not prevent the animal's ability to respond to stress, it contributed to modulating hippocampal functions in both standard and stressful conditions, notably by shaping the microglial response to chronic stress.

Interplay between inflammation and neural plasticity: Both immune activation and suppression impair LTP and BDNF expression.
An increasing number of studies show that both inflammation and neural plasticity act as key players in the vulnerability and recovery from psychiatric disorders and neurodegenerative diseases. However, the interplay between these two players has been limitedly explored. In fact, while a few studies reported an immune activation, others conveyed an immune suppression, associated with an impairment in neural plasticity. Therefore, we hypothesized that deviations in inflammatory levels in both directions may impair neural plasticity. We tested this hypothesis experimentally, by acute treatment of C57BL/6 adult male mice with different doses of two inflammatory modulators: lipopolysaccharide (LPS), an endotoxin, and ibuprofen (IBU), a nonselective cyclooxygenase inhibitor, which are respectively a pro- and an anti-inflammatory agent. The results showed that LPS and IBU have different effects on behavior and inflammatory response. LPS treatment induced a reduction of body temperature, a decrease of body weight and a reduced food and liquid intake. In addition, it led to increased levels of inflammatory markers expression, both in the total hippocampus and in isolated microglia cells, including Interleukin (IL)-1β, and enhanced the concentration of prostaglandin E (PGE). On the other hand, IBU increased the level of anti-inflammatory markers, decreased tryptophan 2,3-dioxygenase (TDO2), the first step in the kynurenine pathway known to be activated during inflammatory conditions, and PGE levels. Though LPS and IBU administration differently affected mediators related with pro- or anti-inflammatory responses, they produced overlapping effects on neural plasticity. Indeed, higher doses of both LPS and IBU induced a statistically significant decrease in the amplitude of long-term potentiation (LTP), in Brain-Derived Neurotrophic Factor (BDNF) expression levels and in the phosphorylation of the AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptor subunit GluR1, compared to the control group. Such effect appears to be dose-dependent since only the higher, but not the lower, dose of both compounds led to a plasticity impairment. Overall, the present findings indicate that acute treatment with pro- and anti-inflammatory agents impair neural plasticity in a dose dependent manner.

ROLE OF BRAIN TLR9 IN INFLAMMATION AND EMOTIONAL BEHAVIOR.

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Álvaro Morcuende, Elena Nieto, Andriana Perdikou, Sofia Antón, Teresa Femenia
Instituto de neurociencias de Alicante UMH-CSIC, Neuropharmacology, Molecular Immunobiology And Behavior, San juan de Alicante, Spain

The immune system has been associated with regulating emotional behaviors. In particular, several types of innate immune receptors of the Toll receptor (TLR) family have been shown to regulate anxiety, depression, and memory. However, the precise role and molecular mechanisms remain to be elucidated. This study aims to evaluate the role of the TLR9 receptor in the brain in a mouse model of depression associated with acute inflammation induced by lipopolysaccharide (LPS). To do so, we analyze the depressive behavior, anxiety and cognitive impairment associated with inflammation in a model of LPS and how an intranasal delivery of TLR9 agonist regulates this response prior to a systemic administration of LPS by evaluating the neurochemical changes in the hippocampus related with pro- and anti-inflammatory pathways, in male and female C57BL6J mice. Our results show that TLR9 stimulation in the brain decreased the depressive-like behavior in the tail suspension test, decreased anxiety in the light-dark box anxiety test in both males and females, and improved episodic memory function in the novel object recognition test males. We found differences in gene expression of pro- and anti-inflammatory cytokines after LPS and TLR9 treatment, alterations in the expression of tight junction proteins and mitochondrial oxidative phosphorylation system. In conclusion, these findings reveal that TLR9 activation in the brain could promote neuroprotective effects conferring resilience to emotional and cognitive-behavioral dysfunction.

Inflammatory Biomarkers in Addictive Disorders.
Substance use disorders are a group of diseases that are associated with social, professional, and family impairment and that represent a high socio-economic impact on the health systems of countries around the world. These disorders present a very complex diagnosis and treatment regimen due to the lack of suitable biomarkers supporting the correct diagnosis and classification and the difficulty of selecting effective therapies. Over the last few years, several studies have pointed out that these addictive disorders are associated with systemic and central nervous system inflammation, which could play a relevant role in the onset and progression of these diseases. Therefore, identifying different immune system components as biomarkers of such addictive disorders could be a crucial step to promote appropriate diagnosis and treatment. Thus, this work aims to provide an overview of the immune system alterations that may be biomarkers of various addictive disorders.

EFFECTS OF PSILOCYBIN ON ACTIVITY-BASED ANOREXIA AND COGNITIVE FLEXIBILITY IN FEMALE RATS

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Laura Milton, Gabriella Farrell, Brian Oldfield, Claire Foldi
Monash University, Department Of Physiology, Melbourne, Australia

Anorexia nervosa (AN) has one of the highest mortality rates of any psychiatric disorder and less than 50% of patients ever recover. Despite this, there are currently no effective medicinal treatments for AN. Psilocybin is currently being explored as a novel therapeutic for AN, and is proposed to act by “breaking down” cognitive inflexibility. To examine the effects of psilocybin on pathological weight loss and cognitive-behavioural flexibility, we used the activity-based anorexia (ABA) model and operant reinforcement tasks. Female Sprague-Dawley rats (n=23; 7 weeks old) were trained to run in wheels and administered psilocybin (1.5 mg/kg) or saline 24h prior to the commencement of ABA, consisting of unlimited access to a running wheel paired with time-limited access to food. A separate cohort of rats (n=31) were trained to nose-poke into one of two operant ports in order to obtain a sucrose reward and administered psilocybin or saline 24h prior to reversal of the reward-paired port. Extinction and reinstatement of responding for sucrose rewards were also examined the day after treatment in a separate cohort of rats (n=22). Psilocybin attenuated the rapid weight loss elicited by ABA conditions, which was driven by both increased food intake ($F_{2,20}$=15.45, p<.0001) and reduced compulsive wheel running ($F_{2,20}$=12.26, p=.0003). Psilocybin also enhanced reversal learning speed ($F_{1,29}$=5.128, p=.031) without effects on extinction ($F_{1,20}$=0.097, p=.758) or reinstatement ($F_{1,20}$=0.081, p=.779), suggesting a specific improvement in flexible learning. Taken together, these findings provide initial support for the therapeutic potential of psilocybin for treating cognitive inflexibility in AN.

EFFECT OF AMITRIPTYLINE ON AFFECTIVE BIASES IN MALE RATS

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Katherine Kamenish
University of Bristol, Ppn, Bristol, United Kingdom

Aims This study investigated the effects of amitriptyline, a tricyclic antidepressant, on affective biases in rats. We test amitriptyline's ability to bias new learning and reverse previously established negative affective biases following acute and 24-hour pretreatment using the affective bias test (ABT). We then test the specificity of the effect using a control reward learning assay. **Methods** The ABT employs a within-subject study design in which animals independently learn to associate a digging substrate with a food reward. One substrate is learnt following a drug treatment manipulation and the other following control. A subsequent preference test is used to determine whether the treatment produced a positive or negative bias toward the treatment-paired substrate. The control reward learning assay involves a similar protocol, but each substrate is paired with either a higher or lower value reward but affective state remains the same throughout. **Results** Amitriptyline positively biased new learning and attenuated a previously learnt negative affective bias 1hr and 24-hour post-treatment. No effects were seen in the reward learning assay, suggesting a specific effect on affective-state induced biases. **Conclusions** These data show similar effects on biases and new learning as previously reported with selective monoamine re-uptake inhibitors e.g., venlafaxine, but contrast with their lack of effect on previously learnt, negative biases. The ability to modulate biases associated with past memories is similar to the effects seen in this assay with the muscarinic antagonist scopolamine which has also been shown clinically to be a rapid-acting antidepressant.

EVALUATION OF THE EFFECTS OF INFLAMMATION AND COMBINED EXPOSURE TO ENVIRONMENTAL TOXICANTS DURING THE PERINATAL PERIOD: A POTENTIAL ETIOLOGICAL FACTOR OF NEURODEGENERATIVE PATHOLOGIES

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Asma Oummadi[1], Sarah Meresse[1], Vanessa Larrigaldie[1], Anthony Laugeray[2], Arnaud Menuet[1], Stéphane Mortaud[1]
[1]INEM, Umr7355 Cnrs, Olréans, France, [2]University of Lausanne, Dept Of Fundamental Neurosciences, Lausanne, Switzerland

Aims In recent decades, the number of neurodegenerative diseases such as Parkinson's or Amyotrophic Lateral Sclerosis (ALS) has steadily increased. It has long been considered that these pathologies are primarily caused by genetic factors, but recent studies tend to show that these diseases are the result of a combination of genetic and environmental factors (like toxins and pesticides). The concept of multiple effects is reinforced by an increasing number of studies that have shown that early exposure, especially during critical periods of brain development, to such agents is likely to alter brain development "fate" through neuronal and inflammatory processes leading eventually to neurodegenerative disorders later in life. Unfortunately, few studies have been implemented to address all these issues simultaneously. **Methods** Pregnant C57Bl6 mice has been subjected to a prenatal low inflammatory challenge (IP LPS injection at 0.008 mg/kg) - followed by a chronic combined exposure to 3 environmental toxicants - β-N-methylamino-L-alanine (BMAA) (50 mg/kg), Glyphosate (GLY) (5 mg/kg), and Ammonium Glufosinate (GLA) (0.2 mg/kg) (protocol A). On the contrary, a chronic maternal pre-toxicants (BMAA/GLY/GLA 3x/week) exposure to a post-natal inflammatory challenge (post-natal day 5 LPS injection) (protocol B) has been settled. Motor, sensory, and emotional abilities have been assessed at different stages of development. **Results** Behavioral results from both protocols showed that a toxicant exposure combined with low inflammation challenge induces motor disorders from adolescence to aging through adulthood. **Conclusion** These data suggest that a mild inflammatory event could modulate a multiple toxins exposure during critical cerebral development phases.

ENDOTHELIAL NMDA RECEPTOR IMPAIRS THE DIFFERENTIATION OF OLIGODENDROCYTES

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Maryline Lecointre[1], Alexandre Béranger[2], Pauline Fadda[1], Mélanie Brosolo[1], Denis Vivien[3], Stéphane Marret[4], Nicolas Guérout[5], Bruno Gonzalez[4]
[1]INSERM U1245 Team 4, Faculty Of Medicine, ROUEN, France, [2]INSERM U1245 Team 4, Faculty Of Medicine, Rouen, France, [3]Normandie University, UNICAEN, Inserm, @Caen-Normandie (BB@C), UMR-S U1237, Physiopathology and Imaging of Neurological Disorders (PhIND), Gip Cyceron, Institut Blood And Brain, Caen, France, [4]Inserm U1245 Team 4, Faculty Of Medicine, Rouen, France, [5]Université de Rouen, Ur3830, Ufr Santé De Rouen, Rouen, France

In human, brain damages, whether genetic or environmental, may depending on the period of development in which they occur cause adverse effects and ultimately lead to birth defects or pathologies that will have long-term effects in adults. Glutamatergic transmission plays a critical role in developmental processes such as neuronal differentiation, migration and plasticity. Previous studies from the laboratory demonstrated a strong expression of endothelial N-methyl-D-aspartate glutamatergic receptor (NMDAR) in the perinatal period. At this time, the contribution of endothelial NMDAR on neurodevelopment remain unknown. The aim of the present study was to investigate the role of endothelial NMDAR in the differentiation of oligodendrocytes. When compared to wild type mice, western blot and immunohistochemical studies performed in Grin1$^{lox/lox}$/VeCad^{cre} mice revealed that CNPase and MBP expression was markedly decreased at postnatal day 15 (P15) in both neocortex and spinal cord. In contrast, PDGFR alpha levels, a marker of oligodendrocyte precursors, were increased. Behavioral studies showed that, at this stage, Grin1$^{lox/lox}$/VeCad^{cre} mice were characterized by a reduced locomotor activity. Partial recovery of these molecular and behavioral defects was found in adults. Altogether, these results suggest that endothelial NMDA invalidation delayed the maturation of oligodendrocytes. They provide first evidence in favor of a key role of the endothelial NMDAR in the establishment of the oligodendrocyte lineage, as it has recently been demonstrated for GABAergic interneurons. They open new research avenues regarding the contribution of this receptor in the vessel-associated migration of oligodendrocytes. *Supported by Rouen University, INSERM, Fondation de France, Blood&Brain Institute, ANR AlcoBrain*

Derry, United Kingdom

Aims: Oral dysbiosis has been associated with the pathophysiology of a number of systemic diseases with underlying inflammatory components, including psychiatric disorders, with growing evidence linking the oral microbiome and depression. The aim of this study was to conduct shotgun metagenomic sequencing (SMS) to characterise the composition and examine functional differences in the oral microbiome in individuals with depression compared to controls. **Methods:** Microbial DNA was extracted from saliva samples from young adults with depression (n=13) and healthy controls (n=19). Microbiome analysis was conducted using SMS. Kraken 2 was used to isolate all the non-human reads. The taxonomic and functional profiling for the depressed and healthy cohorts was obtained separately using the co-assembly method from the SqueezeMeta pipeline v.1.1.2. **Results:** SMS analysis found depression to be associated with significantly decreased alpha diversity (p=0.047) in comparison to healthy controls. Significant differences were also found in one phylum, four genera and seven species between the two cohorts, with two of the species identified being almost exclusively present in the depressed cohort. Functional differential abundance analysis revealed a higher abundance in Kegg Orthologies (KOs) related to eleven molecular functions, including xenobiotic biodegradation and environmental information processing. **Conclusions:** Overall, characteristic differences in the composition of the oral microbiome have been identified in young adults with depression. The clinical importance and their link with pathogenesis of depression require further SMS studies in larger cohorts.

NMDA RECEPTOR AND SYNAPTIC PLASTICITY DYSREGULATION THROUGHOUT DEVELOPMENT IN THE MOUSE FMR1 KNOCKOUT MODEL OF FXS

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Camilla J Lundbye[1,2], Gillian Petroff[2], John Georgiou[1], Graham Collingridge[1,2,3]
[1]University of Toronto, Department Of Physiology, Toronto, Canada, [2]Mount Sinai Hospital, Sinai Health System, Lunenfeld-tanenbaum Research Institute, Toronto, Canada, [3]Toronto Western Hospital, Tanz Centre For Research In Neurodegenerative Diseases, Toronto, Canada

Fragile X Syndrome (FXS) is a developmental autistic syndrome that is diagnosed in childhood. In animal models, one of the more pronounced phenotypes is impaired learning and memory including synaptic plasticity. The goal of this project was to better understand how synaptic deficits developmentally evolve in FXS, and how NMDA receptors (NMDARs) play a role in the dysregulation. We investigated synaptic plasticity through electrophysiological recordings of NMDAR-dependent long-term potentiation (LTP) in five age groups (P10 to P<120) of the Fmr1 knockout (KO) mouse within the CA1 and Dentate Gyrus (DG) areas of the hippocampus. We investigated whether alterations in the normal developmental shift of the ratio between the NMDAR subunits exist and could contribute to the synaptic mechanisms causing deficits seen in the Fmr1 KO. We discovered a consistent decrease in LTP in all five age groups in the DG of the Fmr1 KO mouse compared to littermate wild-type controls whereas in the CA1 we found an age-dependent reduction in LTP at two age groups (P30-40 and P60-80). Through western blotting of hippocampal subfields, we found NMDAR subunits were consistently downregulated in the DG. In the CA1, we found an age-dependent trend for reduced NMDAR subunit expression at the same two age groups where deficits were identified in our LTP experiments. In conclusion, our results are consistent with regional and developmental differences in LTP deficits in Fmr1 KO mice and suggest that a reduction in NMDAR expression may underlie the synaptic plasticity alterations.

Oxidative damage (oxidative stress) has been a prominent topic for scientists for several years. Recently, increased attention has been paid to the influence of oxidative damage on the etiology and pathogenesis of major depressive disorder. Catalase is one of the most important endogenous antioxidant enzymes. If antioxidant mechanisms failed, reactive oxygen species damage the biomolecules followed by progression of the disease. In the present study, we examined the hypothesis that increased oxidative damage and polymorphism in the *CAT* gene (-262 promoter region, rs1001179) are associated with major depressive disorder. Analysis of the rs1001179 catalase polymorphism was performed by polymerase chain reaction and fragment length polymorphism in patients and healthy individuals. TT catalase genotype was more common in patients (4.0 %) compared to controls (0.0 %). More frequent were genotypes CT + TT in patients (40 % vs. 26 %). We did not observe statistically significant differences in the frequency of the rs1001179 catalase polymorphism in patients with major depression. However, genetic variation in antioxidant enzymes could contribute to a certain disease phenotype.

Background: High rates of depression have been identified in student populations. Depression has a complex aetiology caused by a combination of environmental and biological factors. The aim of this research is to investigate demographic and epigenetic factors associated with depression in students. **Methods:** Students who met the criteria for lifetime depression (n=250) and matched controls (n=250) provided a saliva sample and completed an online mental health questionnaire. Methylome profiling using the 850K EPIC array and logistic regression analysis were used to examine associations between methylation patterns and demographic associations with depression. The EPIC Array consists of 850K probes for all gene promoters, gene bodies and CpG islands, covering 99% of RefSeq genes. Raw data (idat files) were processed using the RnBeads pipeline in the R statistical and programming environment. **Results:** Logistic regression analysis found that age and gender were significantly associated with risk for depression, suicide attempt and self-harm. Whole methylome analysis found methylation differences between individuals with depression and matched controls. A number of individual CpG sites met genome wide level FDR significance. Gene ontology analysis of the top 1000 ranked promoters showed highly significant enrichment for immune response consistent with accumulating evidence which supports the relationship between depression and inflammation. **Conclusions:** Our results suggest that many students are starting university with high levels of mental health problems, highlighting the importance of early intervention. Verification of DNA methylation changes in specific genes, detected in saliva, may be a valuable tool for identifying at risk subjects.

Suicidal behaviours and mental health disorders among students commencing college.
The increase in psychological disorders and suicidal behaviour in students is a reason for growing concern. Some may start university with pre-existing problems, while others develop problems during this time. It is important to evaluate mental health and wellbeing early, identifying those at risk. The aim of this study was to compare mental health problems and help-seeking behaviour between students in Northern Ireland (NI) and the Republic of Ireland (ROI). Whilst geographically proximate, the institutions span a cross-border region with distinct education and healthcare systems. First-year undergraduate students (n = 1828) were recruited in September 2019 as part of the World Mental Health International College Student Initiative. Suicidal behaviour, mental health and substance disorders were investigated using the World Mental Health- Composite International Diagnostic Interview. Prevalence of disorders was high, with more ROI students experiencing problems than NI students. Students were significantly more likely to experience mental health problems if they were female (p<0.001), non-heterosexual (p<0.0001), and over the age of 21 (p<0.0001). These findings show that many students are starting university with high levels of psychopathology and suicidal behaviour, highlighting the importance of early intervention which may need to be tailored to different student populations.

RESPONSE EQTL OF GPR56 EXPRESSION ARE ASSOCIATED WITH ANTIDEPRESSANT RESPONSE.

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Marguerite Le Marois[1], El Chérif Ibrahim[1,2], Eleni T. Tzavara[2,3,4,5], Stéphane Jamain[2,6], Raoul Belzeaux[1,2,4]
[1]Institut Neuroscience Timone, Int-umr7289, Marseille, France, [2]Fondation FondaMental, Depression Resistante, Creteil, France, [3]Université Paris Descartes, Translational Psychopharmacology: Novel Targets And Biomarkers, Paris, France, [4]Hôpital Sainte Marguerite, Ap-hm, Marseille, France, [5]Integrative Neuroscience and Cognition Center, Umr 8002, Paris, France, [6]Univ Paris Est Créteil, INSERM, IMRB, Translational Neuropsychiatry, Fondation Fondamental, Créteil, France

Aims Mood disorders are severe and frequent psychiatric conditions, but their pathophysiology remains elusive, and treatment is often difficult. A recent study associated the *GPR56* expression and antidepressant response in individuals with major depressive disorders. To unveil the mechanisms underlying antidepressant response, we aim to identify the genomic loci associated with changes in the *GPR56* expression associated with antidepressant response, also known as response expression quantitative trait loci (reQTL). **Methods** We studied genome-wide genotyping data of peripheral blood mononuclear cells from 144 individuals, comprising healthy volunteers (N=86) and patients (N=58) diagnosed with a major depressive episode, treated with antidepressants, and evaluated 8 weeks later for treatment response. We then assessed the association between SNPs around the 2 Mb region of *GPR56* (*cis*-reQTL) or over the whole genome (*trans*-reQTL) and *GPR56* expression change during the 8-week-follow-up study, through linear regression testing between the genotype of each SNP and the variation of *GPR56* expression. We next generated ROC curves to evaluate the performance of each reQTL to predict the clinical response to treatment. **Results** Several *cis*- and *trans*-reQTL were significantly (p-value<0.001) associated with *GPR56* expression change. Analyses are still ongoing to validate reQTL that are predictive of the clinical response to antidepressants and to specify pathway and functional gene set information. **Conclusions** Promising preliminary results of reQTL for *GPR56* expression and antidepressant treatment were found, and functional enrichment analysis should provide interesting information regarding the pathophysiology of antidepressant response.

Background:
Although the currently available antidepressants are well established in the treatment of major depressive disorder (MDD), there is strong variability in the response of individual patients. Reliable predictors to guide treatment decisions before or in an early stage of treatment are needed. DNA-methylation has been proven a useful biomarker in different clinical conditions, but its importance for mechanisms of antidepressant response has not yet been determined. **Methods:**
80 MDD patients were selected out of >500 participants from the Early Medication Change cohort based on their antidepressant response after four weeks and stratified into clear responders and age- and sex-matched non-responders (N=40, each). Early improvement after two weeks was analyzed as a secondary outcome. DNA-methylation was determined using the Illumina EPIC BeadChip. Epigenome-wide association studies were performed and differentially methylated regions (DMRs) identified using the comb-p algorithm. Enrichment was tested for hallmark gene-sets and in genome-wide association studies of depression and antidepressant response. **Results:**
No epigenome-wide significant differentially methylated positions were found for treatment response or early improvement. Twenty DMRs were associated with response; the strongest in an enhancer region in *SORBS2,* which has been related to cardiovascular diseases and type II diabetes. Another DMR was located in *CYP2C18,* a gene previously linked to antidepressant response. **Conclusions:**
Results pointed towards differential methylation in genes associated with cardiac function, neuroticism, and depression. Linking differential methylation to antidepressant treatment response is an emerging topic and a represents a step towards personalized medicine, potentially facilitating the prediction of patients' response before treatment.

Background: There is a dearth of new mechanistic models for the development of objective tools to diagnose depression and monitor antidepressant responses. In rodent models, administration of acetylcarnitine(LAC) leads to a rapid and sustained antidepressant response by epigenetic regulation of glutamatergic neurons in ventral dentate gyrus neurons. Recently, we found decreased levels of LAC in clinical phenotypes of depression characterized by brain insulin resistance, as showed by increased expression of the insulin docking protein IRS1 in exosomes enriched for L1CAM, a protein highly expressed in the brain. Methods: Here, we used computational approaches and efficiently leveraged biological samples from a previous randomized, placebo-controlled trial with pioglitazone to determine the emergence of the pivotal mitochondrial metabolite LAC in relation to previously described individual predictors of antidepressant responses. Results: Our new findings showed the lowest LAC levels in those subjects with depression characterized by elevated BMI, high reported rates of emotional abuse and decreased leucocytes telomere length(n=47). Furthermore, we used prediction profilers to show that decreased baseline LAC levels, elevated BMI and high reported rates of emotional abuse predict lack of antidepressant response to pioglitazone($p=0.02, r=0.86$) with a stronger ability than each individual measure alone. Discussion: The current findings suggest that integrated factors spanning cellular aging, metabolic function and childhood trauma contribute to define potential new mitochondrial endophenotypes of depression in agreement with the concept of precision medicine. Future studies are needed to further characterize the complex interplay of these multidimensional biological networks, environmental factors with clinical outcomes.

A NOVEL APPROACH TO MEASURE INDIVIDUAL TRAITS REVEALS A PLASTICITY-FOCUSED GENETIC PROFILE OF ANXIETY

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Zoltan K Varga, Diána Pejtsik, László Szente, Zoltán Balogh, Mano Aliczki, Violetta Bartos, Máté Tóth, Eva Mikics
Institute of Experimental Medicine, Laboratory Of Translational Behavioral Neuroscience, Budapest, Hungary

Anxiety disorders are the most prevalent psychiatric illnesses. Animal models, our primary approach to understanding the background of these conditions, often fail to reach clinical relevance. We hypothesize that this is because conventional behavioural readouts represent the fluctuating states rather than the permanent traits of subjects. We suggest a sampling approach of trait anxiety markers based on rethinking rodent models' classical measures. We created summary measures (SuMs) from repeated sampling of popular anxiety tests and compared those with conventional single measurements (SiMs). In contrast to SiMs, SuMs i) revealed correlations of anxiety models, predicted ii) anxiety in future threatening situations and iii) foretold the level of fear generalization. Using these trait-like markers, we conducted a whole-transcriptome RNA-seq analysis on prefrontal cortex samples of 27 rats. We found that SuMs shape the outcome of our analysis quantitatively as well as qualitatively. First, SuMs five-fold enhanced the number of gene discoveries in our study. Second, while SiMs revealed acute stress-related transcripts (38%), the genetic profile of SuMs is dominated by genes of neuronal plasticity (45%). Finally, SuMs revealed five and three times more genes that were previously mentioned in preclinical and clinical literature of mental illness, respectively. In summary, a significant enhancement in the depth and resolution of sampling enables us to trace out stable traits of the animals. Best to our knowledge, this approach identified the highest number of gene targets, and we present the most detailed transcriptomic profile of rodent anxiety so far.

Conserved Serotonergic Background of Experience-Dependent Behavioral Responsiveness in Zebrafish ().
Forming effective responses to threatening stimuli requires the adequate and coordinated emergence of stress-related internal states. Such ability depends on early-life experiences and, in connection, the adequate formation of neuromodulatory systems, particularly serotonergic signaling. Here, we assess the serotonergic background of experience-dependent behavioral responsiveness using male and female zebrafish (). For the first time, we have characterized a period during behavioral metamorphosis in which zebrafish are highly reactive to their environment. Absence of social stimuli during this phase established by isolated rearing fundamentally altered the behavioral phenotype of postmetamorphic zebrafish in a challenge-specific manner, partially due to reduced responsiveness and an inability to develop stress-associated arousal state. In line with this, isolation differentially affected whole-brain serotonergic signaling in resting and stress-induced conditions, an effect that was localized in the dorsal pallium and was negatively associated with responsiveness. Administration of the serotonin receptor 1A partial agonist buspirone prevented the isolation-induced serotonin response to novelty in the level of the whole brain and the forebrain as well, without affecting catecholamine levels, and rescued stress-induced arousal along with challenge-induced behaviors, which together indicates functional connection between these changes. In summary, there is a consistent negative association between behavioral responsiveness and serotonergic signaling in zebrafish, which is well recognizable through the modifying effects of developmental perturbation and pharmacological manipulations as well. Our results imply a conserved serotonergic mechanism that context-dependently modulates environmental reactivity and is highly sensitive to experiences acquired during a specific early-life time window, a phenomenon that was previously only suggested in mammals. The ability to respond to challenges is a fundamental factor in survival. We show that zebrafish that lack appropriate social stimuli in a sensitive developmental period show exacerbated alertness in nonstressful conditions while failing to react adequately to stressors. This shift is reflected inversely by central serotonergic signaling, a system that is implicated in numerous mental disorders in humans. Serotonergic changes in brain regions modulating responsivity and behavioral impairment were both prevented by the pharmacological blockade of serotonergic function. These results imply a serotonergic mechanism in zebrafish that transmits early-life experiences to the later phenotype by shaping stress-dependent behavioral reactivity, a phenomenon that was previously only suggested in mammals. Zebrafish provide new insights into early-life-dependent neuromodulation of behavioral stress-responses.

The swimming plus-maze test: a novel high-throughput model for assessment of anxiety-related behaviour in larval and juvenile zebrafish (Danio rerio).
Larval zebrafish (Danio rerio) has the potential to supplement rodent models due to the availability of resource-efficient, high-throughput screening and high-resolution imaging techniques. Although behavioural models are available in larvae, only a few can be employed to assess anxiety. Here we present the swimming plus-maze (SPM) test paradigm, a tool to assess anxiety-related avoidance of shallow water bodies in early developmental stages. The "+" shaped apparatus consists of arms of different depth, representing different levels of aversiveness similarly to the rodent elevated plus-maze. The paradigm was validated (i) in larval and juvenile zebrafish, (ii) after administration of compounds affecting anxiety and (iii) in differentially aversive experimental conditions. Furthermore, we compared the SPM with conventional "anxiety tests" of zebrafish to identify their shared characteristics. We have clarified that the preference of deeper arms is ontogenetically conserved and can be abolished by anxiolytic or enhanced by anxiogenic agents, respectively. The behavioural readout is insensitive to environmental aversiveness and is unrelated to behaviours assessed by conventional tests involving young zebrafish. Taken together, we have developed a sensitive high-throughput test allowing the assessment of anxiety-related responses of zebrafish regardless of developmental stage, granting the opportunity to combine larva-based state-of-the-art methods with detailed behavioral analysis.

Endocannabinoid interactions in the regulation of acquisition of contextual conditioned fear.
Endocannabinoids (eCBs) anandamide (AEA) and 2-arachidonoylglycerol (2-AG) were shown to be involved in the basis of trauma-induced behavioral changes, particularly contextual conditioned fear, however, their ligand-specific effects and possible interactions are poorly understood. Here we assessed specific eCB effects and interactions on acquisition of contextual conditioned fear employing electric footshocks in a rat model. We selectively increased eCB levels by pharmacological blockade of the degrading enzymes of AEA by URB597 and 2-AG by JZL184 before traumatization either systemically or locally in relevant brain areas, the prelimbic cortex (PrL), ventral hippocampus (vHC) and basolateral amygdala (BLA). Following traumatization, a series of contextual reminders were conducted during which conditioned fear was assessed. While systemic URB597-treatment during traumatization only slightly enhanced the acquisition of contextual conditioned fear, administration of the compound in the PrL and vHC led to the acquisition of stable, lasting conditioned fear, resistant to extinction. These effects of URB597 were blocked by simultaneous administration of JZL184. Similar treatment effects did not occur in the BLA. Treatment effects were not secondary to alterations in locomotor activity or nociception. Our findings suggest that AEA and 2-AG functionally interact in the regulation of acquisition of contextual conditioned fear. AEA signaling in the PrL and vHC is a crucial promoter of fear acquisition while 2-AG potentially modulates this effect. The lack of eCB effects in the BLA suggests functional specificity of eCBs at distinct brain sites.

Differential Roles of the Two Raphe Nuclei in Amiable Social Behavior and Aggression - An Optogenetic Study.
Serotonergic mechanisms hosted by raphe nuclei have important roles in affiliative and agonistic behaviors but the separate roles of the two nuclei are poorly understood. Here we studied the roles of the dorsal (DR) and median raphe region (MRR) in aggression by optogenetically stimulating the two nuclei. Mice received three 3 min-long stimulations, which were separated by non-stimulation periods of 3 min. The stimulation of the MRR decreased aggression in a phasic-like manner. Effects were rapidly expressed during stimulations, and vanished similarly fast when stimulations were halted. No carryover effects were observed in the subsequent three trials performed at 2-day intervals. No effects on social behaviors were observed. By contrast, DR stimulation rapidly and tonically promoted social behaviors: effects were present during both the stimulation and non-stimulation periods of intermittent stimulations. Aggressive behaviors were marginally diminished by acute DR stimulations, but repeated stimulations administered over 8 days considerably decreased aggression even in the absence of concurrent stimulations, indicating the emergence of carryover effects. No such effects were observed in the case of social behaviors. We also investigated stimulation-induced neurotransmitter release in the prefrontal cortex, a major site of aggression control. MRR stimulation rapidly but transiently increased serotonin release, and induced a lasting increase in glutamate levels. DR stimulation had no effect on glutamate, but elicited a lasting increase of serotonin release. Prefrontal serotonin levels remained elevated for at least 2 h subsequent to DR stimulations. The stimulation of both nuclei increased GABA release rapidly and transiently. Thus, differential behavioral effects of the two raphe nuclei were associated with differences in their neurotransmission profiles. These findings reveal a surprisingly strong behavioral task division between the two raphe nuclei, which was associated with a nucleus-specific neurotransmitter release in the prefrontal cortex.

Involvement of 2-arachidonoylglycerol signaling in social challenge responding of male CD1 mice.
Endocannabinoids are strong modulators of emotionality and present a novel target for psychotropic drug development. Increasing evidence suggests that endocannabinoids anandamide and 2-arachidonoylglycerol (2-AG) affect behavior differentially. While the roles of anandamide have been investigated extensively, studies regarding the specific roles of 2-AG became possible only recently, and its involvement in social behaviors has not yet been studied.

Monoacylglycerol lipase inhibition-induced changes in plasma corticosterone levels, anxiety and locomotor activity in male CD1 mice.
The hypothalamus-pituitary-adrenal-axis is strongly controlled by the endocannabinoid system. The specific impact of enhanced 2-arachidonoylglycerol signaling on corticosterone plasma levels, however, was not investigated so far. Here we studied the effects of the recently developed monoacylglycerol lipase inhibitor JZL184 on basal and stress-induced corticosterone levels in male CD1 mice, and found that this compound dramatically increased basal levels without affecting stress responses. Since acute changes in corticosterone levels can affect behavior, JZL184 was administered concurrently with the corticosterone synthesis inhibitor metyrapone, to investigate whether the previously shown behavioral effects of JZL184 are dependent on corticosterone. We found that in the elevated plus-maze, the effects of JZL184 on "classical" anxiety-related measures were abolished by corticosterone synthesis blockade. By contrast, effects on the "ethological" measures of anxiety (i.e. risk assessment) were not affected by metyrapone. In the open-field, the locomotion-enhancing effects of the compound were not changed either. These findings show that monoacylglycerol lipase inhibition dramatically increases basal levels of corticosterone. This endocrine effect partly affects the anxiolytic, but not the locomotion-enhancing effects of monoacylglycerol lipase blockade.

Aim: Asthmatic patients have a higher risk of poor mental health including anxiety and depression. Bidirectional links between lung inflammation and mental health clearly exist, the molecular mechanisms underlying these interactions are not well understood. To gain a better understanding, we performed transcriptomic profiling on different brain regions after inducing lung inflammation (asthma) in mice. **Methodology**: Asthmatic mice were sensitized with either ovalbumin (OVA, 10µg, chicken egg) in alum adjuvant or lipopolysaccharide (LPS, *E. coli*, serotype 026:B6), once/week for 3 consecutive weeks. Mice were then challenged in vapour chambers with either nebulized OVA (1% wt/vol%) or LPS (0.05% (wt/vol%) 20min/day for 3 consecutive days, followed by once/week for 3 additional consecutive weeks. Five brain regions were collected/isolated by hole punch including: hypothalamus, amygdala and lateral adjacent cortex, dorsal hippocampus, periaqueductal gray, dorsal raphe, and the tegmental pontine brainstem. Total RNA was extracted and sequenced using standard protocols for Illumina NovaSeq6000. **Results**: Lung inflammation was confirmed with post-mortem histology using HX&Eo, Alcian blue-PAS, and Masson's Trichrome stains. Our results showed typical asthma features such as peribronchial and perivascular inflammation, airway wall fibrosis and severe mucus production. This study successfully identified a range of single genes and functional gene networks with altered expression in asthma groups versus control. **Conclusion**: Our findings provide insights into the mechanisms underlying neurological changes during asthma. Moreover, these findings may also assist in determining lung-brain pathways that are critical to future drug discovery and efficacy.

Grapefruit juice exerts anti-osteoporotic activities in a prednisolone-induced osteoporosis rat femoral fracture model, possibly via the RANKL/OPG axis.
This study aimed to shed light on the protective and therapeutic anti-osteoporotic effects and mechanisms of action of grapefruit juice (GFJ) on prednisolone-induced osteoporosis a rat femoral fracture model. We found that treating rats with GFJ before and/or after prednisolone-induced osteoporosis resulted in increased bone density, total mineral content, and calcium content to counteract the osteoporotic effects of prednisolone. In parallel, the histological and ultrastructural results of the GFJ-treated groups correlated well with enhanced breaking strength of femurs subjected to a constant load. Furthermore, GFJ treatment before and after prednisolone-induced osteoporosis decreased plasma alkaline phosphatase and tartrate-resistant acid phosphatase activities and increased the level of insulin-like growth factor 1. Mechanistically, our immunohistochemistry study showed that GFJ ameliorated prednisolone-induced osteocalcin depletion, decreased receptor activator of nuclear factor kappa-B ligand (RANKL) expression, and increased osteoprotegerin (OPG) expression. GFJ showed a beneficial anti-osteoporotic effect against prednisolone-induced osteoporosis in rats, possibly via the RANKL/OPG axis, suggesting that GFJ might be a good candidate for developing anti-osteoporotic drugs.

The loss of a loved one inevitably causes emotional distress and failure in trauma processing may result in psychological/psychosomatic disorders. Eye Movement Desensitization and Reprocessing (EMDR) therapy seems to be able to reduce the occurrence of such pathophysiological drifts by inducing horizontal saccadic eye movements via bilateral stimulation. The aim of the present study was to describe acute and longer-lasting physiological effects of EMDR applied to subjects that suffered bereavement. Four women in acute grief were recruited and treated with EMDR therapy. During pre-intervention phase, psychological symptoms associated with trauma, complicated grief, as well as state and trait anxiety were assessed. During EMDR sessions, autonomic (heart rate and heart rate variability – HRV, peripheral temperature changes by means of functional Thermal Imaging), neuroendocrine (salivary cortisol) and psychological parameters (subjective unit of disturbance – SUD - and state anxiety) were evaluated. During post-intervention phase, psychological symptoms were re-assessed. Preliminary results obtained during EMDR sessions point to (i) a lowering of state anxiety levels, (ii) a reduction in cortisol levels, a reduction in heart rate and an increase in vagally-mediated HRV at the end of bilateral stimulation. At the end of the treatment (on average after five EMDR sessions), improved psychological symptoms, decreased heart rate and increased vagally-mediated HRV were observed. These preliminary data suggest that favorable psychological effects of EMDR therapeutic approach might be mediated by its buffering properties over autonomic and neuroendocrine stress responsivity.

Aims Regular physical exercise improves mood, decreasing the risk of developing depressive disorders, and represents a useful tool for a more effective depression treatment, both reducing depressive symptoms and enhancing psychophysical well-being. Muscle cells during exercise secrete myokines that could mediate beneficial effects on several targets including brain. Among the myokines, irisin, recently discovered, displays a neuroprotective effect in cerebral areas involved in cognitive function, memory, learning, and mood. Here, we investigated the potential antidepressant properties of long-term systemic irisin administration in mice by different behavioral tests. Moreover, to evaluate the molecular pathways underlying irisin treatment, we analyzed the expression of irisin precursor (FNDC5), neurotrophic factors, and inflammatory mediators in the brain. **Methods** Young mice were intraperitoneally injected with vehicle or r-irisin (100 µg/kg/weekly) for 1 month. Mouse immobility and locomotor abilities were assessed by the Forced Swim Test (FST), Tail Suspension Test (TST), and Open Field Test (OFT). qRT-PCR assays were performed to analyze the expression of FNDC5, some neurotrophins, growth factors, and interleukins. **Results** Irisin administration decreases the immobility time in TST and FST and increases the time spent in the arena center in OFT. In addition, irisin up-regulates the gene expression of FNDC5, neurotrophins (BDNF, IGF-1), and cytokines (IL-4, IL-6, IL-10, IL-1β) in mouse brain extracts. **Conclusions** Systemic irisin administration is able to induce an antidepressant-like behavior and displays an anxiolytic-like effect probably due to the modulation of endogenous brain factors. However, further studies are needed to better clarify the neuroprotective role of irisin in depressive disorders.

A DOUBLE-BLIND PLACEBO-CONTROLLED ANALYSIS OF QTC INTERVAL PROLONGATION IN NAïVE METHYLPHENIDATE USERS

POSTER SESSION 07 - SECTION: PSYCHOPHARMACOLOGY AND PSYCHIATRIC TREATMENT

Barbara Rogers[1], Nicoleta Stoicea[1,2], Alberto Uribe[1], Wiebke Ackermann[1], Garegin Soghomonyan[1], Sergio Bergese[3]

Introduction: Prolonged QTc interval has been linked to adverse outcomes for chronic methylphenidate users. 1-3 We intended to investigate if naïve methylphenidate users receiving a single dose of Quillivant (methylphenidate extended-release formula) experienced a prolongation of QT interval as seen on 12 lead ECG recorded at 4.5 hour after administration. Methods: Fifty-four adult naïve methylphenidate participants (18-65 years old) received methylphenidate extended-release formula or matching placebo suspension. Pre- and post-operative QTc intervals were calculated. We included in our analysis only participants with a pre-operative QTc of < 450 ms (the normal QT interval is between 400 – 440ms). Results: Only one participant from the placebo group experienced a QTc above 500 ms post-op, seven ranged between 450-500ms, and seven below 450 ms. From the methylphenidate group two participants were above 500 ms, two between 450-500, and eight were below 450 ms. Discussion: We found no conclusive evidence that a single dose of methylphenidate extended-release formula results in QTc interval prolongation. More research is required. References: Kenny, J. LONG-TERM CONSEQUENCES OF ALCOHOL USE IN EARLY ADOLESCENT MICE : FOCUS ON NEUROADAPTATIONS IN GR, CRF AND BDNF.

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Patricia Sampedro-Piquero[1], Román D. Moreno-Fernández[2], Luis J. Santín[3]
[1]Faculty of Psychology. Autonomous University of Madrid., Biological And Health Psychology, Madrid, Spain, [2]Universidad Francisco de Vitoria, Psicología, Madrid, Spain, [3]Universidad de Málaga. Facultad de Psicología., Psicobiología Y Metodología De Las Ciencias Del Comportamiento, Málaga, Spain

Our aim was to assess the cognitive and emotional state, as well as related-changes in the glucocorticoid receptor (GR), the corticotropin-releasing factor (CRF) and the brain-derived neurotrophic factor (BDNF) expression of adolescent C57BL/6J male mice after a five-week two-bottle choice protocol (postnatal day (pd) 21 to pd52). Additionally, we wanted to analyse whether the behavioural and neurobiological effects observed in late adolescence (pd62) lasted until adulthood (pd84). Behavioural testing revealed that alcohol during early adolescence increased anxiety-like and compulsive-related behaviours, which was maintained in adulthood. Concerning cognition, working memory was only altered in late adolescent mice, whereas object location test performance was impaired in both ages. In contrast, novel object recognition remained unaltered. Immunohistochemical analysis showed that alcohol during adolescence diminished BDNF+ cells in the cingulate cortex, the hippocampal CA1 layer and the central amygdala. Regarding hypothalamic-pituitary-adrenal axis (HPA) functioning, alcohol abuse increased the GR and CRF expression ithe hypothalamic paraventricular nucleus and the central amygdala. Besides this, GR density was also higher in the prelimbic cortex and the basolateral amygdala, regardless of the animals' age. Our findings suggest that adolescent alcohol exposure led to long-term behavioural alterations, along with changes in BDNF, GR and CRF expression in limbic brain areas involved in stress response, emotional regulation, and cognition.

Postnatal neurodevelopment is marked by the intense organization and refinement of circuits. Both the exposure to chronic stressors and dopaminergic imbalance are related to neuropsychiatric disorders and, on their own, modulate a range of behaviors. We aimed to investigate if the interaction of both factors acts on behavioral development in male and female mice. Animals were divided into four groups: L-DOPA, Saline, L-DOPA + Maternal Separation (MS), and Saline+MS. The pups were daily intraperitoneally injected with L-DOPA (50mg/kg) or saline and MS groups were also submitted to daily maternal separation for 3 hours/day from P2 until P14. At four weeks old, the animals were tested for exploratory and anxiety-like behavior by actimeter box, open-field test, light-dark box, elevated-plus maze, and feeding suppressed by novelty. Data were analyzed using Two-Way ANOVA and Tukey posthoc. We found that females injected with L-DOPA showed decreased anxiety-like behavior. On the other hand, the SM females injected with L-DOPA showed increased exploratory- and anxiety like-behavior. Males injected with L-DOPA showed an increase in exploratory- and anxiety-like behavior. Our results show that imbalance in dopaminergic signaling during early-development disrupted anxiety-like behavior in a sex-specific way. We also observed that early-life stress together with dopaminergic imbalance caused an opposite response of the dopaminergic imbalance alone in females. We need further studies to investigate the mechanisms behind these results and understand this interaction and to improve our understanding of the dopaminergic system during development. Finally, our results reinforce the importance of using both males and females in research.

Impairment of motor but not anxiety-like behavior caused by the increase of dopamine during development is sustained in zebrafish larvae at later stages.
Many neuropsychiatric disorders are associated with both dopaminergic (DAergic) and developmental hypotheses. Since DAergic receptors are expressed in the developing brain, it is possible that alterations in dopamine (DA) signaling may impair brain development and consequent behavior. In our previous study, using a zebrafish model, we showed that an increase of DA during the 3 to 5 days postfertilization (dpf) developmental window (an important window for GABAergic neuronal differentiation) affects the motor behavior of 5 dpf larvae. In this study, we set out to determine whether these behavioral alterations were sustained in larvae at older stages (7 and 14 dpf). To test this hypothesis, we chronically treated zebrafish larvae from 3 to 5 dpf with DA. After washing the drug, we recorded and analyzed the first 5 and 30 min of the motor behavior of 5, 7, and 14 dpf subjects. We analyzed mobile episodes, distance traveled, time mobile, distance traveled per mobile episode, time in movement per mobile episode, and distance traveled per time mobile. We showed, once again, that an increase of DA during the 3 to 5 dpf developmental window reduces the number of movement episodes initiated by 5 dpf larvae. We also detected a decrease of other motor behavior parameters in 5 dpf DA-treated larvae. We observed that these alterations are sustained in the 7 dpf larvae. However, we did not see these general locomotor alterations in the 14 dpf larvae. Moreover, we detected a decrease of distance traveled and an increase of time of locomotion per episode in the first 5 min of behavioral analyses in 14 dpf DA-treated larvae. To test if the alterations in the first 5 min were due to anxiety-like behavior, we used a light/dark preference paradigm. We recorded 5dpf, 7dpf, and 14dpf larvae for 5 min and analyzed time of freezing, preference for light or dark, number of entries to the dark, percentage of time in the light. We observed that 5dpf larvae treated with DA showed more freezing, less passages to the dark, and more time spent in the light as compared to their control counterparts. But 7dpf and 14dpf larvae did not show these alterations. Taken overall, therefore, our results suggest that DA does play a role in the development of zebrafish motor behavior, and, furthermore, that some behaviors are

more sensitive than others to the effects of DAergic imbalances during development.

SEX-SPECIFIC CONSEQUENCES OF PRECONCEPTION STRESS ON THE DEVELOPMENT OF DENDRITIC SPINES AND DENDRITIC LENGTH IN THE HIPPOCAMPAL FORMATION OF RATS

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Feyza Tas[1], Jörg Bock[2], Neta Ferdman[3], Micah Leshem[3], Katharina Braun[2]
[1]Otto von Guericke University, Institute of Biology, Department Of Zoology And Developmental Neurobiology, Magdeburg, Germany, [2]Otto von Guericke University, Institute of biology, Department Of Zoology And Developmental Neurobiology, Magdeburg, Germany, [3]University of Haifa, School Of Psychological Science, Haifa, Israel

Our previous work in rats revealed that preconception stress (PCS), i.e. stress experienced by females prior to fertilization, affects neuronal development in the prefrontal cortex of their offspring. In extension of this study we analyzed the impact of PCS on neuronal and synaptic development in the hippocampal formation. Young adult female rats were exposed to unpredictable variable stressors for one week and then mated. Granular neurons in the dentate gyrus and pyramidal neurons in the CA1 (dorsal) region of adult male and female offspring from mothers exposed to PCS and from control mothers were quantitatively compared. Parameters analysed included dendritic length, dendritic spine number and spine frequency. In the dentate gyrus dendritic length was increased only in female PCS offspring, but not in male animals. In contrast, in the CA1 region basal dendritic length and basal spine number were increased only in male PCS offspring, but not in their sisters. The PCS-induced development of longer dendrites and higher spine numbers may reflect a higher level of synaptic connectivity within the hippocampal formation and perhaps also a more intensive input into the hippocampal formation from other brain regions. Based on our behavioral findings, where we observed increased anxiety and reduced social behavior in both genders of PCS offspring, it is tempting to speculate that stress prior to fertilization leads to an excessive intra- and interconnectivity of the hippocampal formation of the offspring and thereby mediate pathological behavioral outcomes.

PLATINUM NANOPARTICLE-BASED MICROREACTORS PROTECT AGAINST THE BEHAVIORAL AND NEUROBIOLOGICAL CONSEQUENCES OF CHRONIC STRESS EXPOSURE

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Milena Viana[1], Rafael Hirata[1], Roberto Oliveira[1], Mariana Silva[1], Jéssica Lemes[1], Bárbara Garcia[1], Adam Armada-Moreira[2], Ana Maria Sebastião[3], Sandra Vaz[3], Isabel Céspedes[4]
[1]Federal University of São Paulo, Biosciences, Santos, Brazil, [2]Linkoping University, Department Of Science And Technology, Norrkoping, Sweden, [3]University of Lisbon, Instituto De Medicina Molecular, Lisbon, Portugal, [4]Federal University of São Paulo (UNIFESP), Departamento De Morfologia E Genética, são paulo, Brazil

Excitotoxicity is described as the exacerbated activation of glutamate receptors that leads to neuronal damage and cell death. Astrocytes are responsible for the clearance of 80–90% of synaptically released glutamate. Chronic stress renders neurons vulnerable to excitotoxicity and has been associated to neuropsychiatric disorders. Platinum nanoparticles (Pt-NP) assembled with glutamate dehydrogenase and glutathione reductase have shown *in vitro* activity against excitotoxicity. The purpose of the present study was to investigate the *in vivo* efficacy of these nanoparticles on the behavioral and neurobiological effects of chronic stress exposure. Rats were either unstressed or exposed for 2 weeks to an unpredictable chronic mild stress paradigm (UCMS), administered intra-ventral hippocampus with Pt-NP (with or without the blockage of astrocyte functioning), and seven days later tested in the elevated T-maze (ETM; Experiment 1). The ETM allows the measurement of two defensive responses, avoidance and escape, in terms of psychopathology respectively related to generalized anxiety and panic disorder. Locomotor activity in an open field was also measured. Since previous evidence shows that stress inhibits adult neurogenesis, we evaluated the effects of the different treatments on the number of cells expressing the marker of migrating neuroblasts doublecortin (DCX) in the hippocampus (Experiment 2). Results showed that UCMS induces anxiogenic effects, increases locomotion, and decreases the number of DCX cells, effects that were counteracted by Pt-NP administration. This is the first study to demonstrate the *in vivo* efficacy of Pt-NP against the behavioral and neurobiological effects of chronic stress exposure. THE OVERFUNCTION OF ADENOSINE A2A RECEPTORS IN THE BASOLATERAL AMYGDALA IS NECESSARY AND SUFFICIENT TO TRIGGER BEHAVIOURAL MODIFICATIONS INDUCED BY REPEATED STRESS

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Rodrigo Cunha[1], Ana Patrícia Simões[1], Nuno Machado[1], Nélio Gonçalves[2], Paula Canas[2]
[1]University of Coimbra, Faculty Of Medicine, Coimbra, Portugal, [2]University of Coimbra, Cnc – Center For Neuroscience And Cell Biology, Coimbra, Portugal

Background: Chronic stress impairs mood and memory, an effect prevented by blocking adenosine A_{2A} receptors ($A_{2A}R$) (PNAS 112:7833,2015), which are upregulated in basolateral amygdala (BLA) upon stress. We now tested if blunting $A_{2A}R$ only in amygdala neurons normalizes behavioural alterations caused by repeated restraint stress (RS) and if this is mimicked by overactivating $A_{2A}R$ signalling. **Methods:** One week prior to handling or 14 days RS (4h daily), male adult Wistar rats were injected bilaterally in BLA with lentivectors encoding either a $A_{2A}R$-silencing short hairpin ($shA_{2A}R$) or control (shCTR) (*Nature Comm*7:11915,2016) or AAV5-CaMKIIα-optoA_{2A}R-mcherry (chimera to light-activate $A_{2A}R$ transducing systems; *Mol Psychiatry* 20:1339,2015) or AAV5-CaMKIIα-mcherry (control) and implanted optic fibers. After RS or after light stimulation for 6 consecutive days (8 trains each with 3000 light pulses of 50ms duration over 5min, 10min inter-train interval), rats (n=9-23/group) were behaviourally tested before assessing long-term potentiation (LTP) in amygdala slices (*Neuropsychopharmacol* 41:2862,2016). **Results:** Compared to control rats, RS rats injected with shCTR had no alteration of locomotion but displayed despair-based depression (forced-swimming), reward-based deficits (splash), increased anxiety (elevated plus-maze) and hampered memory (modified Y-maze, object displacement). BLA-$A_{2A}R$ down-regulation prevented RS-induced behavioral modification without altering locomotion and blunted exacerbated amygdala LTP. Chronic opto$A_{2A}R$ BLA stimulation increased anxiety, anhedonic-like and depressive-like behaviour, impaired spatial working memory and increased BLA-LTP magnitude. **Conclusions:** This shows a pivotal role of amygdala $A_{2A}R$ controlling RS-induced modifications and prompts $A_{2A}R$ as targets to manage mood-related disorders. DISSOCIATING RECOVERED FROM UNRECOVERED INDIVIDUALS FOLLOWING TREATMENT IN AN ANIMAL MODEL OF PTSD REVEALS DIFFERENCES IN EXCITATORY-INHIBITORY BALANCE IN THE HIPPOCAMPUS.

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Ishita Sarkar, Maja Snippe-Strauss, Gal Richter-Levin
University of Haifa, Sagol Department Of Neurobiology, Haifa, Israel

The accepted approach for testing the effects of pharmacological treatment in animal models of PSTD remains examining the averaged impact of such treatment. However, clinically only a minority of patients show complete or partial remission. To bridge this discrepancy we used individual *'Behavioural Profiling*' (BP) approach to classify animals as '*treatment-responders' (TR)* or 'non-responders' (NR) to SSRI treatment. We bolstered the behavioral profiling approach by further elucidating molecular and electrophysiological changes amongst the categorized animals. We employed the (BP) analysis in an animal model of PTSD to separate between '*Trauma Exposed-Affected' (EA)* and '*Exposed-Unaffected'* individuals. *EA* animals were treated for one month with fluoxetine (SSRI). We further separated the *EA* population into *(TR)* or *(NR)*. Hippocampal tissue was collected, and the levels of $GABA_A$-α1, $GABA_A$-α2, GluN1, GluN2A were analyzed using western blots. In another set of animals, we conducted electrophysiological recording in the dorsal dentate gyrus to examine changes in local circuit activity and in LTP. As with human patients, only about 40% of the affected population responded to fluoxetine. These results strongly support the translational power of the model. Hippocampal tissue investigation indicated changes in GABAergic and Glutamatergic receptors' subunit expression between *TR*, *NR,* and healthy controls. Electrophysiological recording in the hippocampal dentate gyrus also revealed significant alterations in local circuit activity between *TR* and *NR*. Together, the findings suggest that a shift in excitatory-inhibitory balance in the hippocampus is associated with being responsive to drug treatment. This hints towards different molecular mechanisms leading to normalized behavior after recovery.

IMPACT OF MITOFUSIN 2 ON ACCUMBENS-ASSOCIATED BEHAVIORS AND UNDERLYING NEUROBIOLOGICAL MECHANISMS

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Alessandro Chioino
EPFL, Sv-bmi, Lausanne, Switzerland

Mitochondrial dysfunction is increasingly being implicated in the aetiology of psychiatric disorders, but the underlying cellular and molecular mechanisms have not been fully identified. Previous work has established a link between trait anxiety and the expression of the mitochondrial fusion protein mitofusin 2 (Mfn2) in the nucleus accumbens (NAc) (Gebara et al., 2021), essential for motivation and goal-directed behavior. Here, we investigated the consequences of downregulating Mfn2 in the NAc for coping behavior, dendritic structure and synaptic physiology of NAc D1 medium spiny neurons (MSNs). To induce conditional mfn2 knockout in D1-MSNs, we employed a tamoxifen-dependent mouse line (Mfn2lox/lox-Drd1aCreERT2) or a viral vector (AAV1-Dyn-CRE) in the Mfn2lox/lox mouse line. Then, we evaluated animals' performance in the forced swim test, an effort-based motivation task. Mfn2 deletion in NAc D1-MSNs promoted the adoption of passive coping behaviors, as indicated by increased immobility. This was associated with a decreased activation of NAc shell neurons during the task, as revealed by cFos mapping. Ex vivo patch-clamp recordings from biocytin-filled D1-MSNs indicated that mfn2 deletion induced a reduction in dendritic complexity and in the frequency of excitatory inputs, as compared to wild-type D1-MSNs. Mitochondria qualitative assay via MitodsRed showed changes in organelles circularity and length. These results indicate that Mfn2 downregulation impacts the morphology and electrophysiological properties of accumbal D1-MSNs, leading to impaired engagement of the NAc during effort-related behavior. Our findings can deepen our understanding of the mechanisms underlying motivational disorders and pave the way for the development of novel treatment strategies to depression.

IMPLICATION OF THE VIP/VPAC1/2 SYSTEM IN THE REGULATION OF STRESS AND ANXIETY REACTIONS IN RODENTS

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Federico Ferro[1], Veronica Fontebasso[1], Magali Basille[2], David Vaudry[2], Karl Ebner[1]
[1]University of Innsbruck, Dep. Toxicology & Pharmacology, Innsbruck, Austria, [2]Université de Rouen, Département De Biologie, Rouen, France

Vasoactive intestinal polypeptide (VIP) is a 28-amino-acid long peptide identified in the peripheral and central nervous system (CNS). Notably, within the CNS, VIP and its cognate VPAC receptors are highly expressed in stress and anxiety-related brain areas, such as amygdala, BNST, lateral septum as well as some cortical and hypothalamic structures. Although of these neuroanatomical findings, the role of VIP in stress and anxiety function is not well characterized. Accordingly, our first aim was to examine whether emotional stressors change VIP and/or VPAC1/2 receptor expression in selected brain areas. Therefore, quantitative real-time PCR technique was used to analyze VIP and VPAC1/2 mRNA transcript levels of rats exposed either to acute or chronic stress. Our results show stress-induced changes in VIP and VPAC1/2 receptor transcript levels in distinct brain areas. Our second aim was to investigate the effects of intracerebral VIP infusions on anxiety-related behaviors of rodents. Thus, C57Bl6/J male mice were administered either with VIP or vehicle and tested in the light/dark or elevated plus-maze test. We found that VIP-injected animals show a reduction of time spent in aversive zones of the behavioral tasks compared to vehicle-injected controls, suggesting an anxiogenic-like effect. Taken together, these data implicate a stress-induced upregulation of the central VIP/VPAC receptor system and, highlight a crucial role of VIP signaling in the regulation of stress and anxiety functions.

The Levodopa-Induced Depression Model Exhibits Negative Geotaxis Deficits and Differential Gene Expression in Males and Females.
More than 320 million people live with depression in the world, a disorder that severely limits psychosocial functioning and diminishes quality of life. The prevalence of major depression is almost two times higher in women than in men. However, the molecular mechanisms of its sex-specific pathophysiology are still poorly understood. is an established model for neurobiological research of depression-like states, as well as for the study of molecular and genetic sex differences in the brain. Here, we investigated sex-specific effects on forced-climbing locomotion (negative geotaxis) and gene expression of a fly model of depression-like phenotypes induced by levodopa administration, which was previously shown to impair normal food intake, mating frequency, and serotonin concentration. We observed that both males and females show deficits in the forced-climbing paradigm; however, modulated by distinct gene expression patterns after levodopa administration. Our results suggest that models can be a valuable tool for identifying the molecular mechanisms underlying the difference of depressive disorder prevalence between men and women.

Transient Administration of Dopaminergic Precursor Causes Inheritable Overfeeding Behavior in Young Adults.
Imbalances in dopaminergic signaling during development have been indicated as part of the underlying neurobiology of several psychiatric illnesses, including schizophrenia, major depression, bipolar disorder, and food addiction. Yet, how transient manipulation of dopaminergic signaling influences long-lasting behavioral consequences, or if these modifications can induce inheritable traits, it is still not understood. In this study, we used the model to test if transient pharmacological activation of the dopaminergic system leads to modulations of feeding and locomotion in adult flies. We observed that transient administration of a dopaminergic precursor, levodopa, at 6 h, 3 days or 5 days post-eclosion, induced overfeeding behavior, while we did not find significant effects on locomotion. Moreover, this phenotype was inherited by the offspring of flies treated 6 h or 3 days post-eclosion, but not the offspring of those treated 5 days post-eclosion. These results indicate that transient alterations in dopaminergic signaling can produce behavioral alterations in adults, which can then be carried to descendants. These findings provide novel insights into the conditions in which environmental factors can produce

transgenerational eating disorders.

Introduction: Chronic stress is the main environmental factor in the aetiology of depression and it is known that this type of stress may cause alterations in brain regions such as the hippocampus. Nevertheless, changes in a cellular basis are still a subject of study. ***Objective:*** The analysis of microglial cells and immature neurons in the dentate gyrus (DG) of stressed mice. ***Methods:*** C57BL/6J mice were subjected to Social Defeat Stress model (SDS), consisting of 6 days of social isolation prior to 10 days of stressor. The DG was analysed using immunohistochemistry techniques against Iba1 (microglia) and DCX (immature neurons) following image analysis (ImageJ) to obtain morphological and distribution data of microglial somas. Furthermore, hippocampal neurogenesis was assessed through stereological quantification of DCX+ cells (Visiopharm). ***Results***: An increase in soma size under chronic stress conditions was shown, as well as a less circular and more ameboid soma. These changes were observed mainly in the infrapyramidal blade of the DG. According to microglial cells distribution parameters, the granular cell layer (GCL) was the region which presented the highest microglial density under SDS. Regarding hippocampal neurogenesis, a decrease in the number of DCX+ Type 2-3 cells was observed in the whole DG. ***Conclusion:*** All these results offer a more profound insight of stress changes at a cellular level and could contribute to a better understanding of neurobiological basis in pathologies such as depression. **Projects: PSI2017-83408-P (MINECO) and P20 00460 (Consejería de Conocimiento, Investigación y Universidades, Junta de Andalucía). ABNORMAL INTERNEURON NETWORK CONFIGURATION IN A MODEL OF FRAGILE X ASSOCIATED NEUROPSYCHIATRIC DISORDERS

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Fragile X-associated neuropsychiatric disorders (FXAND) have been identified that result from premutation extension of CGG repeats in the Fragile X gene. These coincide or even precede the neurodegenerative late-onset Fragile X-associated tremor/ataxia syndrome (FXTAS), but in contrast to the latter, suitable animal models for the investigation of mechanisms causing FXAND are still missing. Here we describe a mouse model generated by inducible pre-and postnatal activation of a 99CGG transgene expression in the nervous system, resulting in hyperactivity of adolescent mutants and strongly increased anxiety-like behaviour in young adults in the absence of overt motor symptoms. Substantial inclusion load was found to accumulate in these animals in the cerebellum, but also in the ventral hippocampus (VH) and basolateral amygdala (BLA). Electrophysiological analysis revealed augmented gamma oscillations in the VH emerging during adolescence, and enhanced excitability in the adult, but not adolescent BLA. These findings were mirrored by the number of parvalbumin interneurons in these limbic regions, which were increased in number during adolescence but reduced in adulthood. Our data together suggest a disturbed maturation of limbic brain areas during postnatal development and aberrant configuration of the inhibitory network as putative cause for the altered network function and increased anxiety in this FXAND model.

Antibiotic-induced gut dysbiosis leads to activation of microglia and impairment of cholinergic gamma oscillations in the hippocampus.
Antibiotics are widely applied for the treatment of bacterial infections, but their long-term use may lead to gut flora dysbiosis and detrimental effects on brain physiology, behavior as well as cognitive performance. Still, a striking lack of knowledge exists concerning electrophysiological correlates of antibiotic-induced changes in gut microbiota and behavior. Here, we investigated changes in the synaptic transmission and plasticity together with behaviorally-relevant network activities from the hippocampus of antibiotic-treated mice. Prolonged antibiotic treatment led to a reduction of myeloid cell pools in bone marrow, circulation and those surveilling the brain. Circulating Ly6C inflammatory monocytes adopted a proinflammatory phenotype with increased expression of CD40 and MHC II. In the central nervous system, microglia displayed a subtle activated phenotype with elevated CD40 and MHC II expression, increased IL-6 and TNF production as well as with an increased number of Iba1 + cells in the hippocampal CA3 and CA1 subregions. Concomitantly, we detected a substantial reduction in the synaptic transmission in the hippocampal CA1 after antibiotic treatment. In line, carbachol-induced cholinergic gamma oscillation were reduced upon antibiotic treatment while the incidence of hippocampal sharp waves was elevated. These alterations were associated with the global changes in the expression of neurotrophin nerve growth factor and inducible nitric oxide synthase, both of which have been shown to influence cholinergic system in the hippocampus. Overall, our study demonstrates that antibiotic-induced dysbiosis of the gut microbiome and subsequent alteration of the immune cell function are associated with reduced synaptic transmission and gamma oscillations in the hippocampus, a brain region that is critically involved in mediation of innate and cognitive behavior.

Auxiliary α2δ1 and α2δ3 Subunits of Calcium Channels Drive Excitatory and Inhibitory Neuronal Network Development.
VGCCs are multisubunit complexes that play a crucial role in neuronal signaling. Auxiliary α2δ subunits of VGCCs modulate trafficking and biophysical properties of the pore-forming α1 subunit and trigger excitatory synaptogenesis. Alterations in the

expression level of α2δ subunits were implicated in several syndromes and diseases, including chronic neuropathic pain, autism, and epilepsy. However, the contribution of distinct α2δ subunits to excitatory/inhibitory imbalance and aberrant network connectivity characteristic for these pathologic conditions remains unclear. Here, we show that α2δ1 overexpression enhances spontaneous neuronal network activity in developing and mature cultures of hippocampal neurons. In contrast, overexpression, but not downregulation, of α2δ3 enhances neuronal firing in immature cultures, whereas later in development it suppresses neuronal activity. We found that α2δ1 overexpression increases excitatory synaptic density and selectively enhances presynaptic glutamate release, which is impaired on α2δ1 knockdown. Overexpression of α2δ3 increases the excitatory synaptic density as well but also facilitates spontaneous GABA release and triggers an increase in the density of inhibitory synapses, which is accompanied by enhanced axonaloutgrowth in immature interneurons. Together, our findings demonstrate that α2δ1 and α2δ3 subunits play distinct but complementary roles in driving formation of structural and functional network connectivity during early development. An alteration in α2δ surface expression during critical developmental windows can therefore play a causal role and have a profound impact on the excitatory-to-inhibitory balance and network connectivity. The computational capacity of neuronal networks is determined by their connectivity. Chemical synapses are the main interface for transfer of information between individual neurons. The initial formation of network connectivity requires spontaneous electrical activity and the calcium channel-mediated signaling. We found that, in early development, auxiliary α2δ3 subunits of calcium channels foster presynaptic release of GABA, trigger formation of inhibitory synapses, and promote axonal outgrowth in inhibitory interneurons. In contrast, later in development, α2δ1 subunits promote the glutamatergic neurotransmission and synaptogenesis, as well as strongly enhance neuronal network activity. We propose that formation of connectivity in neuronal networks is associated with a concerted interplay of α2δ1 and α2δ3 subunits of calcium channels.

SEX- AND TIME-DEPENDENT ALTERATIONS OF SYNAPTIC PLASTICITY IN AIC-NACC PATHWAY INDUCED BY ACUTE STRESS

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Manon Gauthier[1], Virginie Lardeux[2], Emilie Dugast[2], Marcello Solinas[2], Pauline Belujon[1]
[1]INSERM U1084, Lnec-university Of Poitiers, Poitiers, France, [2]Inserm U1084, Lnec-university Of Poitiers, Poitiers, France

Chronic stress is a major risk factor for the development of psychiatric disorders. Functional connectivity between the anterior insular cortex (aIC) and the nucleus accumbens core (NAcc) has been shown to be dysregulated in several of these disorders. Here, we investigated how exposure to acute stress disrupts insular inputs to the NAcc, measured by synaptic plasticity. Immediately after exposure to acute restraint stress or 24h later, *in vivo* extracellular recordings from NAcc neurons were performed in male and female rats in response to single-pulse stimulation of the aIC. High frequency stimulation (HFS) to the aIC was applied after a baseline period to measure changes in synaptic plasticity. In control male rats, aIC-HFS predominantly induced a long-term depression (LTD) in NAcc neurons whereas in stressed rats, it induced an LTP. In control female rats, aIC-HFS induced mostly an LTP whereas in the stressed group it produced no changes, suggesting either a loss of the ability to generate synaptic plasticity or an occlusion of LTP. 24 hours after stress, aIC-HFS predominantly evoked an LTP in both males and females. Our data indicate that males and females show different synaptic plasticity in the aIC-NAcc pathway under normal conditions, and different changes in synaptic efficacy in their acute response to stress. Furthermore, 24 hours after stress, only females demonstrated similar synaptic plasticity than control rats compared to males. These neurobiological responses might contribute to sex differences described in stress-related pathologies such as depression and anxiety.

Gyrophoric acid (GA) is a secondary metabolite of various lichens, such as *Umbilicaria hirsuta*. Its effects on brain structures or behavior in living organisms have not been studied yet. The study aimed to analyze the potential antidepressant effects of daily administered GA in laboratory Wistar rats. In addition, we wanted to determine the ability of GA to cross the blood-brain barrier using isolated endothelial cells (BMEC) from two-week-old Wistar rats. Then, the potential antidepressant effects of GA were tested on Wistar male rats with immobilization and stress-induced depression. Pregnant females were stressed using restriction of mobility in the last week of gestation three times a day for 45 minutes each, three following days. GA (10 mg/kg body weight) was administered on daily basis for 30 days in 10% ethanol solution. Our preliminary results suggest that GA crosses BBB and thus could directly affect brain structures. During the depression, GA potentiated the process of neurogenesis, assessed as a significant increase in Ki67 positive cells in the hilus of the hippocampus ($P<0.01$). Besides, GA influenced the number of mature NeuN positive neurons in the CA1 layer of the hippocampus ($P<0.01$). The behavior showed increased time spent in open arms in EPM. The “shy” untreated animals eliminated the number of center crossing and rearing ($P<0.05$), the “lion-hearted” GA treated counterparts prolonged the spending time in open arms of the EPM test ($P<0.05$). GA shows some antidepressant effects and thus could be used as a supplement treatment of depression in the future.

Melatonin mitigates hippocampal and cognitive impairments caused by prenatal irradiation.
Formation of new neurons and glial cells in the brain is taking place in mammals not only during prenatal embryogenesis but also during adult life. As an enhancer of oxidative stress, ionizing radiation represents a potent inhibitor of neurogenesis and gliogenesis in the brain. It is known that the pineal hormone melatonin is a potent free radical scavenger and counteracts inflammation and apoptosis in brain injuries. The aim of our study was to establish the effects of melatonin on cells in the hippocampus and selected forms of behaviour in prenatally irradiated rats. The male progeny of irradiated (1 Gy of gamma rays; n = 38) and sham-irradiated mothers (n = 19), aged 3 weeks or 2 months, were used in the experiment. Melatonin was administered daily in drinking water (4 mg/kg b. w.) to a subset of animals from each age group. Prenatal irradiation markedly suppressed proliferative activity in the dentate gyrus in both age groups. Melatonin significantly increased the number of proliferative BrdU-positive cells in hilus of young irradiated animals, and the number of mature NeuN-positive neurons in hilus and granular cell layer of the dentate gyrus in these rats and in CA1 region of adult irradiated rats. Moreover, melatonin significantly improved the spatial memory impaired by irradiation, assessed in Morris water maze. A significant correlation between the number of proliferative cells and cognitive performances was found, too. Our study indicates that melatonin may decrease the loss of hippocampal neurons in the CA1 region and improve cognitive abilities after irradiation.

The Plant-Derived Compound Resveratrol in Brain Cancer: A Review.
Despite intensive research, malignant brain tumors are among the most difficult to treat due to high resistance to conventional therapeutic approaches. High-grade malignant gliomas, including glioblastoma and anaplastic astrocytoma, are among the most devastating and rapidly growing cancers. Despite the ability of standard treatment agents to achieve therapeutic concentrations in the brain, malignant gliomas are often resistant to alkylating agents. Resveratrol is a plant polyphenol occurring in nuts, berries, grapes, and red wine. Resveratrol crosses the blood–brain barrier and may influence the central nervous system. Moreover, it influences the enzyme isocitrate dehydrogenase and, more importantly, the resistance to standard treatment via various mechanisms, such as O6-methylguanine methyltransferase. This review summarizes the

anticancer effects of resveratrol in various types of brain cancer. Several in vitro and in vivo studies have presented promising results; however, further clinical research is necessary to prove the therapeutic efficacy of resveratrol in brain cancer treatment.

Future Aspects for Cannabinoids in Breast Cancer Therapy.
Cannabinoids (CBs) from provide relief for tumor-associated symptoms (including nausea, anorexia, and neuropathic pain) in the palliative treatment of cancer patients. Additionally, they may decelerate tumor progression in breast cancer patients. Indeed, the psychoactive delta-9-tetrahydrocannabinol (THC), non-psychoactive cannabidiol (CBD) and other CBs inhibited disease progression in breast cancer models. The effects of CBs on signaling pathways in cancer cells are conferred via G-protein coupled CB-receptors (CB-Rs), CB1-R and CB2-R, but also via other receptors, and in a receptor-independent way. THC is a partial agonist for CB1-R and CB2-R; CBD is an inverse agonist for both. In breast cancer, CB1-R expression is moderate, but CB2-R expression is high, which is related to tumor aggressiveness. CBs block cell cycle progression and cell growth and induce cancer cell apoptosis by inhibiting constitutive active pro-oncogenic signaling pathways, such as the extracellular-signal-regulated kinase pathway. They reduce angiogenesis and tumor metastasis in animal breast cancer models. CBs are not only active against estrogen receptor-positive, but also against estrogen-resistant breast cancer cells. In human epidermal growth factor receptor 2-positive and triple-negative breast cancer cells, blocking protein kinase B- and cyclooxygenase-2 signaling via CB2-R prevents tumor progression and metastasis. Furthermore, selective estrogen receptor modulators (SERMs), including tamoxifen, bind to CB-Rs; this process may contribute to the growth inhibitory effect of SERMs in cancer cells lacking the estrogen receptor. In summary, CBs are already administered to breast cancer patients at advanced stages of the disease, but they might also be effective at earlier stages to decelerate tumor progression.

Neuronal analysis and behaviour in prenatally gamma-irradiated rats.
The intrauterinal development in mammals represents a very sensitive period of life in relation to many environmental factors, including ionizing radiation (IR). The developing nervous system is particularly vulnerable to IR, and the consequences of exposure are of importance because of its potential health risks. The aim of our work was to assess whether prenatal irradiation of rats on the 17th day of embryonic development with a dose of 1 Gy would affect the formation of new cells and the number of mature neurons in the hippocampus and the selected forms of behaviour in the postnatal period. Male progeny of irradiated and control females was tested at ages of 3 weeks, 2 and 3 months. The number of mitotically active cells in the gyrus dentatus (GD) of the hippocampus was significantly reduced in irradiated rats aged 3 weeks. In irradiated rats aged 2 months, a significant reduction of mature neurons in CA1 area and in GD of the hippocampus was observed. The IR negatively influenced the spatial memory in Morris water maze, significantly decreased the exploratory behaviour and increased the anxiety-like behaviour in elevated plus-maze in rats aged 2 months. No significant differences were observed in animals aged 3 months compared with controls of the same age. A significant correlation between the number of mature neurons in the hilus and of the cognitive performances was found. Our results show that a low dose of radiation applied during the sensitive phase of brain development can influence the level of neurogenesis in the subgranular zone of GD and cause an impairment of the postnatal development of mental functions.

Resveratrol enhances the chemopreventive effect of celecoxib in chemically induced breast cancer in rats.
Resveratrol and celecoxib were used as chemopreventive agents in animal models of carcinogenesis, and exert antiproliferative and proapoptotic effects on cancer cells. Therefore, the aim of this study was to evaluate whether combining resveratrol with celecoxib may exert more potent anticarcinogenic effects than the single agents. Mammary carcinogenesis was initiated in 70 female Sprague-Dawley rats with N-methyl-N-nitrosourea (NMU). The chemoprevention with resveratrol, celecoxib, and their combination started 2 weeks before the first carcinogen dose and lasted until the end of the experiment. Tumor incidence and frequency, latency period, tumor volume, the expression of cyclooxygenase 2 (COX2) and growth differentiation factor 15 (GDF15), and also the formation of reactive oxygen species were analyzed using different methods. In addition, the levels of resveratrol and its metabolites in blood and selected tumor tissues were determined by high-performance liquid chromatography. Finally, the anticancer effects of the reagents were studied in the human breast cancer cell line MCF-7. Celecoxib as a single agent significantly decreased tumor frequency, prolonged tumor latency, and decreased the total number of malignant tumors compared with the NMU conditions. Tumor volume was nonsignificantly reduced (0.68±0.25 vs. 0.93±0.28 cm3). Importantly, the addition of resveratrol to celecoxib reduced tumor volume by 60% compared with celecoxib alone (from 0.68±0.25 to 0.27±0.07 cm3, $P<0.05$). Furthermore, the combination of resveratrol and

celecoxib reduced tumor frequency by 29% compared with celecoxib alone (P=0.53). Tumor latency was not influenced by this combination compared with celecoxib alone (126.56±3.45 vs. 120.71±4.08 days). In addition, COX2 mRNA and immunoreactive protein stained on tumor sections were reduced and GDF15 protein increased significantly by the combination studied compared with the NMU conditions. In agreement with these data, a significant reduction in reactive oxygen species in blood lymphocytes of the combination was detected, which may have contributed toward the cancer-preventive effects of this application. This study showed that in NMU-induced mammary cancer in rats, the combination of resveratrol and celecoxib led to a significant reduction in all tumor parameters. In addition, in terms of tumor volume, the combination was more efficient than celecoxib as a single agent.

A combination of resveratrol and melatonin exerts chemopreventive effects in N-methyl-N-nitrosourea-induced rat mammary carcinogenesis.
The neurohormone melatonin is primarily involved in the regulation of circadian rhythms, but also acts as an antioxidant and anticarcinogenic agent, especially in breast cancer. Resveratrol (3,5,4'-trihydroxy-trans-stilbene) is a widely known polyphenolic agent from red wine, which has been shown to exert antioxidant, anti-inflammatory and anticarcinogenic effects. The objective of this study was therefore to investigate the effects of melatonin in combination with resveratrol in a rat model of experimental mammary carcinogenesis. Female Sprague-Dawley rats aged 31 days were used in the experiment. Mammary carcinogenesis was induced by N-methyl-N-nitrosourea (NMU), which was administered in two intraperitoneal doses (50 mg/kg of body weight). Chemoprevention with resveratrol and melatonin started 2 weeks before the first dose of NMU and lasted until the end of the experiment. The basic parameters evaluated were: tumour incidence, latency period, tumour frequency per group and tumour volume. In addition, oestrogen receptors ERα and ERß, melatonin receptor MT1, proliferating cell nuclear antigen and vascular endothelial growth factor were determined by immunohistochemical staining. The combination of resveratrol and melatonin reduced tumour incidence by approximately 17% and significantly decreased the quantity of invasive and in-situ carcinomas. Food intake declined in the second and seventh weeks after the administration of carcinogen. Resveratrol in combination with melatonin returned food intake to the level of intact controls. Resveratrol in combination with melatonin has some protective effects on NMU-induced rodent breast cancer. Further studies are necessary to confirm these effects of this promising combination.

EFFECTS OF CORTICOSTERONE ON ASTROCYTIC GENE EXPRESSION IN MODELS OF DEPRESSION

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Xiaoyan Lin, Farah Chamaa, Hubert Fiumelli, Pierre Magistretti
KAUST, Biological And Environmental Sciences And Engineering, Thuwal, Saudi Arabia

Depression is a psychiatric disorder greatly influenced by stress and high corticosterone levels. Lately, emerging evidence highlights the importance of astrocyte dysfunction in the neurobiology of depression, where lactate, the end-product of astrocytic aerobic glycolysis, regulates gene expression involved in neuroprotection. Our aim is to investigate the effect of stress and corticosterone in the impairment of astrocyte-neuron coupling, and the possibility of restoration with lactate treatment. Accordingly, we have used cultures of mouse neocortical astrocytes, and the chronic unpredictable stress (CUS) or corticosterone models of depression. In vitro, we have detected that, prolonged treatment of the astrocytic cultures with corticosterone downregulates mRNA and protein expression of glucose transporter 1 (GLUT1) and lactate transporter Monocarboxylate Transporter 4 (MCT4), suggesting an impairment in the astrocyte-neuron lactate shuttle (ANLS). Moreover, this treatment induced an increase in the expression of thioredoxin-interacting protein (TXNIP), a marker of pathological oxidative stress associated with glucose and lipid metabolism dysfunction. In mice, CUS or daily corticosterone injections, induced increased anxiety and social avoidance, detected by a battery of behavioral tests including social interaction test. Lactate treatment in both models promoted resilience to stress and anxiety, and rescued social avoidance to levels that were comparable with control mice. We are currently analyzing transcriptomic modulations of genes related to energy metabolism in the hippocampus and the prefrontal cortex of the two animal models, treated or not with lactate. Alterations of these genes in astrocytes suggest that the ANLS is an important pathway targeted in stress and psychiatric disorders.

SOCIAL DEFEAT STRESS INDUCES MICROGLIAL ALTERATIONS AND IMPAIRED CELL SURVIVAL IN THE HYPOTHALAMUS ACCORDING TO BEHAVIORAL PHENOTYPE

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Maria Inmaculada Infantes-Lopez[1,2], Emma Zambrana-Infantes[2,3], Patricia Chaves-Peña[3], Andrea Nieto-Quero[1,2,3], Jose Munoz-Martin[1], Carmen Pedraza[2,3], Margarita Perez-Martin[1,2]

Stress is the main environmental cause for depression, known to cause brain immune alterations. As major brain immune cells, microglia undergo transcriptional and, consequently, morphological changes that result in tissue damage, including new cell generation impairment. Even so, few brain regions have been thoroughly studied, excluding key regulators as the hypothalamus, in which this process remains partially unknown. Moreover, there is a poor understanding in physiology related to behavioral outcome. Therefore, it would be interesting to study the relationship between microglia and cell proliferation in stressed mice while controlling for behavior. Here, we used the social defeat stress (SDS) paradigm as a depression-inducing protocol in 8-week-old male C57BL/6J mice for 10 consecutive days. Intruder mice behavior was analyzed to assess depression using behavioral tests and K-means clustering. By immunohistochemical and imaging procedures, microglial morphology, and distribution, as well as cell survival, were analyzed in the hypothalamic paraventricular, ventromedial and arcuate nucleus. Finally, statistical mediation analysis was conducted to evaluate the relationship among variables. Results show mice response to SDS was different, being half the mice resilient and half sensitive to depressive-like symptoms. Microglial morphological activation was enhanced in the ventromedial and arcuate nucleus, especially in stress sensitive animals. Similar results were observed in cell survival, which was particularly affected in sensitive mice. Strikingly, these cell survival changes were statistically mediated by microglial activation. As a conclusion, hypothalamic regions were found to respond differently to stress, accordingly to behavioral outcome, in terms of microglial activation and subsequent decrease in cell survival.

Behavioural states like anxiety, preference selection and social interaction allow organisms to adapt and communicate appropriately, thus promoting homeostasis and survival. Changes in the brain that regulate behavioural states involve multiple sensory-related circuits as well as sub-cortical structures. Our previous study demonstrated that the interstitial nucleus of posterior limb of anterior commissure, lateral (IPACL) plays a role in regulating aversive and avoidance behaviours via specific CRH circuits. However, how neurons achieve this in the IPACL remains unknown. We investigate this using deep brain Ca^{2+} imaging in IPACL with miniature microscope, coupled with longitudinal imaging through different contexts (innate fear, anxiety, place preference and social interaction) in freely moving animals. Using machine learning methods tailored for time series analyses, we are able to identify ensembles of neurons in IPACL that encode specific behaviours, which can be classified into groups encoding negative, positive and neutral valences. We find that a majority of the neurons in IPACL are correlated with negative valence, confirming the involvement of IPACL in coping with aversive situations. In addition, we also find ensembles of IPACL neurons that are involved in social interaction. To understand the molecular mechanisms underlying the neuronal activity that mediates behaviour, we perform activity trapping with FOS^{TRAP} mice and genes expression of those cells will be identified through spatial sequencing. In summary, we propose that IPACL is a novel hub for mediating both emotional and social behaviours. This will contribute to the further understanding how extended amygdala engages and regulates fundamental behaviours for adaptation and survival.

CHRONIC CORTICOSTERONE ADMINISTRATION IN MICE ALTERS BEHAVIOURAL STRATEGY IMPLEMENTATION BY MODIFYING STRIATAL-DEPENDENT MOTOR AND COGNITIVE ACTIVITY

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Stéphanie Cramoisy, Lidia Cabeza, Bahrie Ramadan, Christophe Houdayer, Stéphanie Dumontoy, Emmanuel Haffen, Fanchon Bourasset, Yvan Peterschmitt

Chronic corticosterone administration (CCA) mimics excessive activation of the hypothalamo-pituitary-adrenal axis in rodents, resulting in a pathological phenotype commonly used to model human distress-related disorders such as anxiety and depression. Previous studies conducted in our laboratory demonstrated that CCA negatively impacts motor and cognitive processes in mice, and leads to suboptimal decision-making in particular. However, further investigation is needed to better characterize these impairments. The present study further evaluated the consequences of CCA on the balance between habits and goal-directed behavioural strategies in adult C57BL/6JRJ male mice. Dorsal striatum-dependent habit learning was assessed using a cross-maze-based single-solution paradigm (response learning) and a rotarod motor learning task. Thereafter, a dual-solution task (place learning) enabled additional examination of the balance between striatum and hippocampus-dependent strategies. Since behavioural control necessary for adaptive decision-making is supported by both learning processes, this study will allow identify the approach distressed mice mostly rely on: a striatum-based egocentric strategy or a hippocampus-based allocentric one. Our preliminary data indicate that CCA leads to delayed striatum-dependent learning in both the motor and response learning tasks, in line with a delayed behavioural initiation during the decision-making process. Furthermore, the indecision observed in some distressed mice could refer to a difficulty in implementing a decision-making strategy. Thus, our results support that CCA modulates learning by regulating the striatum-hippocampal balance. Imbalanced striatum-hippocampus-dependent behavioral strategies might therefore underlie aberrant decision-making induced by chronic distress in pathological conditions.

ACUTE STRESS DRIVES CHANGES IN CO-TRANSMITTER IDENTITY IN SEROTONERGIC NEURONS THAT PROMOTE SUSTAINED FEAR

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Huiquan Li[1], Li Ling[1], Wuji Jiang[1], Cong Chen[2], Don Cleveland[2], Nicholas Spitzer[1]

Fear is an essential emotion for survival. Acquired fear responses are typically specific to the cue or context associated with an aversive stimulus (conditioned fear), but they can also spread to other cues or contexts (producing generalized fear). The cellular and circuit mechanisms by which fear is generalized remain unclear. We have studied neurotransmitter plasticity underlying fear generalization. Using a VGLUT3-Cre transgenic mouse line crossed with a Rosa-mCherry reporter line to permanently label VGLUT3+ neurons, we found that two weeks after intense footshock stress, a subset of serotonergic (5-HT) neurons in the lateral wings of the dorsal raphe (lwDR) of shocked mice had switched co-transmitter from glutamate/VGLUT3 to GABA/GAD67. We then discovered that the proportions of VGLUT3 and GAD67 in 5-HT^{lwDR} neurons in human PTSD subjects and age-matched controls were similar to those in stressed and non-stressed mice. To study the causal relationship between the transmitter switch and generalized fear, we injected Cre-dependent adeno-associated viruses in SERT-Cre mice to express exogenous VGLUT3 or suppress expression of GAD1 in 5-HT^{lwDR} neurons and measured the effect on fear responses by recording the time mice spent freezing in a novel chamber. Expression of exogenous VGLUT3 partially reduced generalized fear caused by footshock stress and expression of GAD1 entirely erased it. Prompt delivery of fluoxetine, a selective serotonin reuptake inhibitor, blocked both the glutamate-to-GABA switch in the lwDR and generalized fear responses. However, when delivery of fluoxetine was delayed, no blockade was observed. Identification of this plasticity underlying fear generalization may provide therapeutic opportunities.

Microglial migration mediated by ATP-induced ATP release from lysosomes.
Microglia are highly motile cells that act as the main form of active immune defense in the central nervous system. Attracted by factors released from damaged cells, microglia are recruited towards the damaged or infected site, where they are involved in degenerative and regenerative responses and phagocytotic clearance of cell debris. ATP release from damaged neural tissues has been suggested to mediate the rapid extension of microglial process towards the site of injury. However, the mechanisms of the long-range migration of microglia remain to be clarified. Here, we found that lysosomes in microglia contain abundant ATP and exhibit Ca(2+)-dependent exocytosis in response to various stimuli. By establishing an efficient in vitro chemotaxis assay, we demonstrated that endogenously-released ATP from microglia triggered by local microinjection of ATPγS is critical for the long-range chemotaxis of microglia, a response that was significantly inhibited in microglia treated with an agent inducing lysosome osmodialysis or in cells derived from mice deficient in Rab 27a (ashen mice), a small GTPase required for the trafficking and exocytosis of secretory lysosomes. These results suggest that microglia respond to extracellular ATP by releasing ATP themselves through lysosomal exocytosis, thereby providing a positive feedback mechanism to generate a long-range extracellular signal for attracting distant microglia to migrate towards and accumulate at the site of injury.

P2Y4 receptor-mediated pinocytosis contributes to amyloid beta-induced self-uptake by microglia.
Brain disturbances, like injuries or aberrant protein deposits, evoke nucleotide release or leakage from cells, leading to microglial chemotaxis and ingestion. Recent studies have identified P2Y12 purinergic receptors as triggers for microglial chemotaxis and P2Y6 receptors as mediators for phagocytosis. However, pinocytosis, known as the internalization of fluid-phase materials, has received much less attention. We found that ATP efficiently triggered pinocytosis in microglia. Pharmacological analysis and knockdown experiments demonstrated the involvement of P2Y4 receptors and the phosphatidylinositol 3-kinase/Akt cascade in the nucleotide-induced pinocytosis. Further evidence indicated that soluble

amyloid beta peptide 1-42 induced self-uptake in microglia through pinocytosis, a process involving activation of P2Y4 receptors by autocrine ATP signaling. Our results demonstrate a previously unknown function of ATP as a "drink me" signal for microglia and P2Y4 receptors as a potential therapeutic target for the treatment of Alzheimer's disease.

Neuronal activity regulates neurotransmitter switching in the adult brain following light-induced stress.
Neurotransmitter switching in the adult mammalian brain occurs following photoperiod-induced stress, but the mechanism of regulation is unknown. Here, we demonstrate that elevated activity of dopaminergic neurons in the paraventricular nucleus of the hypothalamus (PaVN) in the adult rat is required for the loss of dopamine expression after long-day photoperiod exposure. The transmitter switch occurs exclusively in PaVN dopaminergic neurons that coexpress vesicular glutamate transporter 2 (VGLUT2), is accompanied by a loss of dopamine type 2 receptors (D2Rs) on corticotrophin-releasing factor (CRF) neurons, and can lead to increased release of CRF. Suppressing activity of all PaVN glutamatergic neurons decreases the number of inhibitory PaVN dopaminergic neurons, indicating homeostatic regulation of transmitter expression in the PaVN.

Exercise enhances motor skill learning by neurotransmitter switching in the adult midbrain.
Physical exercise promotes motor skill learning in normal individuals and those with neurological disorders but its mechanism of action is unclear. We find that one week of voluntary wheel running enhances the acquisition of motor skills in normal adult mice. One week of running also induces switching from ACh to GABA expression in neurons in the caudal pedunculopontine nucleus (cPPN). Consistent with regulation of motor skills, we show that the switching neurons make projections to the substantia nigra (SN), ventral tegmental area (VTA) and ventrolateral-ventromedial nuclei of the thalamus (VL-VM). Use of viral vectors to override transmitter switching blocks the beneficial effect of running on motor skill learning. We suggest that neurotransmitter switching provides the basis by which sustained running benefits motor skill learning, presenting a target for clinical treatment of movement disorders.

Analysis of microglial migration by a micropipette assay.
Microglial cells have important roles in maintaining brain homeostasis, and they are implicated in multiple brain diseases. There is currently interest in investigating microglial migration that results in cell accumulation at focal sites of injury. Here we describe a protocol for rapidly triggering and monitoring microglial migration by using a micropipette assay. This protocol is an adaptation of the axon turning assay using microglial cells. Chemoattractants released from the micropipette tip produce a chemotactic gradient that induces robust microglial migration. In combination with microscopic imaging, this assay allows simultaneous recording of cell movement and subcellular compartment trafficking, along with quantitative analysis. The actual handling time for the assay takes ~2-3 h in total. The protocol is simple, inexpensive and convenient to set up, and it can be adopted to examine cell migration in multiple cell types, including cancer cells with a wide range of chemical signals.

A novel size-based sorting mechanism of pinocytic luminal cargoes in microglia.
Microglia are the resident immune cells in the CNS and play diverse roles in the maintenance of CNS homeostasis. Recent studies have shown that microglia continually survey the CNS microenvironment and scavenge cell debris and aberrant proteins by phagocytosis and pinocytosis, and that reactive microglia are capable to present antigens to T cells and initiate immune responses. However, how microglia process the endocytosed contents and evoke an immune response remain unclear. Here we report that a size-dependent selective transport of small soluble contents from the pinosomal lumen into lysosomes is critical for the antigen processing in microglia. Using fluorescent probes and water-soluble magnetic nanobeads of defined sizes, we showed in cultured rodent microglia, and in a cell-free reconstructed system that pinocytosed proteins become degraded immediately following pinocytosis and the resulting peptides are selectively delivered to major histocompatibility complex class II (MHC-II) containing lysosomes, whereas undegraded proteins are retained in the pinosomal lumen. This early size-based sorting of pinosomal contents relied on the formation of transient tunnel between pinosomes and lysosomes in a Rab7- and dynamin II-dependent manner, which allowed the small contents to pass through but restricted large ones. Inhibition of the size-based sorting markedly reduced proliferation and cytokine release of cocultured CD4(+) T cells, indicating that the size-based sorting is required for efficient antigen presentation by microglial cells. Together, these findings reveal a novel early sorting mechanism for pinosomal luminal contents in microglial cells, which may explain how microglia efficiently process protein antigens and evoke an immune response.

Decoding Neurotransmitter Switching: The Road Forward.
Neurotransmitter switching is a form of brain plasticity in which an environmental stimulus causes neurons to replace one neurotransmitter with another, often resulting in changes in behavior. This raises the possibility of applying a specific environmental stimulus to induce a switch that can enhance a desirable behavior or ameliorate symptoms of a specific pathology. For example, a stimulus inducing an increase in the number of neurons expressing dopamine could treat Parkinson's disease, or one affecting the number expressing serotonin could alleviate depression. This may already be producing successful treatment outcomes without our knowing that transmitter switching is involved, with improvement of motor function through physical activity and cure of seasonal depression with phototherapy. This review presents prospects for future investigation of neurotransmitter switching, considering opportunities and challenges for future research and describing how the investigation of transmitter switching is likely to evolve with new tools, thus reshaping our understanding of both normal brain function and mental illness.

ACUTE PSYCHOLOGICAL STRESS: EFFECTS ON HIPPOCAMPAL NEUROGENESIS AND THE ROLE OF MICROGLIA

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Andrea Nieto-Quero[1,2], Patricia Chaves-Peña[1,3], Maria Inmaculada Infantes-Lopez[2,3], Emma Zambrana-Infantes[1,2], Sara Tabbai[1,2], Jose Munoz-Martin[3], Margarita Perez-Martin[2,3], Carmen Pedraza[1,2]
[1]University of Malaga, Department Of Psychobiology And Methodologies Of Behavioural Sciences, Malaga, Spain, [2]Biomedical Research Institute of Malaga (IBIMA), Neurosciences, Malaga, Spain, [3]University of Malaga, Department Of Cell Biology, Genetics And Physiology, Malaga, Spain

Among all the factors that can contribute to the onset of psychopathological disorders, stress is the main environmental factor. The hippocampus is one of the most sensitive regions to the harmful effects of stress, in which the neurogenic process is impaired. On the other hand, under stress situations, microglia are also affected and can trigger a proinflammatory response, acting as anti-neurogenic cells and releasing cytokines and other proinflammatory molecules. Knowing what happens in the early stages of stress may be relevant to investigate the temporal aspects of the development of stress-associated psychopathological disorders, and even their possible treatment. Therefore, after subjecting C57BL/6J mice for 2 hours to an acute and intense stress procedure called WIRS (water immersion restraint stress), data were analyzed to study microglia, cell proliferation and neuronal maturation. In addition, a mediation analysis study was conducted for data integration. The results revealed that the applied acute stress is sufficiently intense to induce an increase in the number of microglia, accompanied by morphometric changes, as well as negatively affecting the neuronal maturational process. Furthermore, these data suggest that effects on the neurogenic process mediate the microglial response to an intense acute stressor. This leads to the conclusion that this may be the initial mechanism for any intense stress response, or may even be the first steps in the development of the response to a chronic stressor.

Do changes in microglial status underlie neurogenesis impairments and depressive-like behaviours induced by psychological stress? A systematic review in animal models.
Stress may have a negative effect on mental health and is the primary environmental risk factor in the aetiology of depression. Nevertheless, the neurobiological mechanisms underlying this mood disorder remain poorly characterized. The hippocampus is a target structure of the adverse effects of stress, and hippocampal neurogenesis plays a crucial role. However, we do not know the mechanisms by which stress impacts neurogenesis. Recent studies indicate that changes in neuroinflammation, primarily via microglial cells, may play an essential role in this process. However, the relationship between stress, microglial changes, and alterations in neurogenesis and their involvement in the development of depression is poorly characterized. For this reason, this systematic review aims to synthesise and evaluate current studies that have investigated the relationship between these variables. Taken together, the revised data, although not entirely conclusive, seem to suggest that microglial changes induced by psychological stress regulate neurogenesis and in turn may be responsible for the development of depressive-like behaviours, but other factors that influence these stressful experiences should not be dismissed.

Effects of the LPA Receptor Deficiency and Stress on the Hippocampal LPA Species in Mice.
Lysophosphatidic acid (LPA) is an important bioactive lipid species that functions in intracellular signaling through six characterized G protein-coupled receptors (LPA). Among these receptors, LPA is a strong candidate to mediate the central effects of LPA on emotion and may be involved in promoting normal emotional behaviors. Alterations in this receptor may induce vulnerability to stress and predispose an individual to a psychopathological disease. In fact, mice lacking the LPA receptor exhibit emotional dysregulation and cognitive alterations in hippocampus-dependent tasks. Moreover, the loss of this receptor results in a phenotype of low resilience with dysfunctional coping in response to stress and induces anxiety and several behavioral and neurobiological changes that are strongly correlated with mood disorders. In fact, our group proposes

that maLPA1-null mice represent an animal model of anxious depression. However, despite the key role of the LPA-LPA-pathway in emotion and stress coping behaviors, the available information describing the mechanisms by which the LPA-LPA-pathway regulates emotion is currently insufficient. Because activation of LPA requires LPA, here, we used a Matrix-Assisted Laser Desorption/ Ionization mass spectrometry-based approach to evaluate the effects of an LPA receptor deficiency on the hippocampal levels of LPA species. Additionally, the impact of stress on the LPA profile was also examined in both wild-type (WT) and the Malaga variant of LPA1-null mice (maLPA-null mice). Mice lacking LPA did not exhibit gross perturbations in the hippocampal LPA species, but the LPA profile was modified, showing an altered relative abundance of 18:0 LPA. Regardless of the genotype, restraint stress produced profound changes in all LPA species examined, revealing that hippocampal LPA species are a key target of stress. Finally, the relationship between the hippocampal levels of LPA species and performance in the elevated plus maze was established. To our knowledge, this study is the first to detect, identify and profile LPA species in the hippocampus of both LPA-receptor null mice and WT mice at baseline and after acute stress, as well as to link these LPA species with anxiety-like behaviors. In conclusion, the hippocampal LPA species are a key target of stress and may be involved in psychopathological conditions.

Effects of genetic deletion versus pharmacological blockade of the LPA receptor on depression-like behaviour and related brain functional activity.

Animal models of psychopathology are particularly useful for studying the neurobiology of depression and characterising the subtypes. Recently, our group was the first to identify a possible relationship between the LPA receptor and a mixed anxiety-depression phenotype. Specifically, maLPA-null mice exhibited a phenotype characterised by depressive and anxious features. However, the constitutive lack of the gene encoding the LPA receptor () can induce compensatory mechanisms that might have resulted in the observed deficits. Therefore, in the present study, we have compared the impact of permanent loss and acute pharmacological inhibition of the LPA receptor on despair-like behaviours and on the functional brain map associated with these behaviours, as well as on the degree of functional connectivity among structures. Although the antagonist (intracerebroventricularly administered Ki16425) mimicked some, but not all, effects of genetic deletion of the LPA receptor on the results of behavioural tests and engaged different brain circuits, both treatments induced depression-like behaviours with an agitation component that was linked to functional changes in key brain regions involved in the stress response and emotional regulation. In addition, both Ki16425 treatment and LPA receptor deletion modified the functional brain maps in a way similar to the changes observed in depressed patients. In summary, the pharmacological and genetic approaches could ultimately assist in dissecting the function of the LPA receptor in emotional regulation and brain responses, and a combination of those approaches might provide researchers with an opportunity to develop useful drugs that target the LPA receptor as treatments for depression, mainly the anxious subtype.This article has an associated First Person interview with the first author of the paper.

EXCESSIVE MIDBRAIN GLUTAMATERGIC TONE PROMOTE ANXIETY VIA DYSREGULATION OF AMYGDALA PRINCIPAL NEURONS

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Thomas Contesse[1], Christelle Glangetas[2], Léa Royon[1], Hugo Fofo[1], François Georges[2], Sebastian Fernandez[1], Jacques Barik[1]
[1]IPMC UMR7275, CNRS-Université Côte d'Azur, Laboratory Of Physiopatology Of Neuronal Circuits And Behavior, Valbonne, France, [2]Institute of Neurodegenerative Disease, Gironde, Bordeaux, France

Anxiety disorders are a major human blight afflicting a high proportion of the population and are difficult to diagnose. A poor efficiency in the existing treatments reveal the lack of knowledge about the neuronal network regulating anxiety. While the neuronal substrate of anxious behaviour is incredibly complex, a core feature of anxiety disorders is the hyperactivity of the amygdala. Here, we study if this hyperactivity can be linked to excessive glutamatergic tone. We relied on viral tool and transgenic mice to specifically target a midbrain glutamatergic population connecting to the basolateral amygdala. Modulation of these afference by acute selective optogenetic activation and chemogenetic inhibition was not sufficient to change basal anxiety levels in mice. However, a chronic optogenetic activation of this glutamatergic projection led to increased anxiety levels. Furthermore, using electrophysiological tools, we correlated these anxious behaviours with plastic synaptic changes onto principal neurons of the basolateral amygdala. Finally, we used our finding to show that anxiety-disorders like symptoms induced with chronic social defeat cannot be reversed by chronic chemogenetic silencing of these glutamatergic inputs to the amygdala. Taken together, our study uncovered a new pathway that may contribute to the induction of anxiety-disorders through dysregulation of amygdala activity. Preventive approaches targeting this pathway could be relevant to prevent the induction of stress related anxiety-disorders and need further investigation.

The cytoplasmic polyadenylation element binding protein-3 (CPEB3) is a functional amyloid, whose importance for long-term memory consolidation of mammals has been widely demonstrated. Recently, it has also been pointed out as a potential risk gene for Post-Traumatic Stress Disorder (PTSD). This mental health disorder is triggered by the exposure to a traumatic event that manifests with anguish, intrusive memories, and negative mood changes. So far, there is no efficient treatment for PTSD other than symptomatic palliative care. According to this, we propose CPEB3's active amyloid state as a possible therapeutic target to block the consolidation of traumatic memories through the action of the anti-amyloidogenic polyglutamine binding peptide 1 (QBP1). Once we had demonstrated that murine CPEB3 is being inhibited by QBP1 peptide in vitro, we have developed and characterized a transgenic mouse that constitutively expresses QBP1. We first showed the innocuity of this peptide and the normal locomotor activity and anxiety levels of QBP1 mice. Secondly, hippocampal-dependent memories were tested, reflecting that they are impaired at long term and that just new memories are being affected. Finally, analyzing aversive memories we demonstrated that they were also compromised by the presence of QBP1 peptide, which was revealed by a reduction of fear-induced anxiety and a correlative decrease in mCPEB3 oligomerization extracted from hippocampal samples. All this work suggests QBP1 peptide is a promising lead compound for prevention and therapy of PTSD and acute stress disorder (ASD).

CONTINUOUS STRESS AFFECTS KAINATE RECEPTOR-DEPENDENT INHIBITION BY PARVALBUMIN NEURONS IN THE MOUSE AMYGDALA.

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Maria Ryazantseva[1], Maj Liiwand[1], Vasilii Shteinikov[1], Vootele Voikar[2], Sari Lauri[1]

Continuous stress is a risk factor for psychiatric disorders, including generalized anxiety, post-traumatic stress disorder, and major depressive disorder. The amygdala plays a significant role in processing emotions and regulates anxiety responses to stressful and arousing situations. Recent evidence suggests that continuous stress induces hyperexcitability of the amygdala's basolateral nucleus (BLA). Parvalbumin interneurons (PV+) innervate principal neurons (PN) perisomatically, providing potent inhibition. We have demonstrated previously that kainate receptors containing the GluK1 subunit modulate PV+ excitability to support the feedforward inhibition for the PN in the lateral amygdala (LA). Here we investigated the effect of continuous restraint stress on mouse LA to dissect the role of GluK1 in the PV+ neurons in stress-induced anxiety. In situ hybridization data show that most cells in LA expressing GluK1 are GAD1+ inhibitory neurons, including PV+ neurons. Our electrophysiological data from WT and PV+ cell-specific GluK1 knockout mice demonstrate that tonic activity of GluK1 in PV+ neurons regulates PN excitability in LA, and this effect is abolished after continuous restraint stress. Behavioral experiments demonstrated that the conditional knock-out of GluK1 in the LA led to an anxiety-like phenotype in mice. Overall, these data suggest that a loss of tonic activity of GluK1 containing kainate receptors in the PV+ neurons contributes to stress-related changes in LA excitability associated with anxiety.

AIMS: Pleiotrophin (PTN) is a cytokine that modulates behavioural effects of ethanol and neuroinflammation. PTN is an endogenous inhibitor of Receptor Protein Tyrosine Phosphatase (RPTP) β/ζ. RPTPβ/ζ inhibition reduces binge-like drinking in mice. We studied RPTPβ/ζ role in regulation of chronic ethanol consumption and alcohol-derived neuroimmune alterations. **METHODS:** Male and female adolescent C57BL/6J mice followed an intermittent access to ethanol (IAE) 2-bottle choice protocol. Before each drinking session MY10 (60 mg/kg, i.g.), a small-molecule RPTPβ/ζ inhibitor, or vehicle was administered. Ethanol consumption was measured. After the 4-week protocol, brains were removed for immunohistochemistry of Iba-1, GFAP and doublecortin (DCX). In the acute ethanol experiments, mice were treated with MY10 one hour before a 6 g/kg ethanol (i.p.) administration. Eighteen hours post-injection, brains were dissected and subjected to the same immunohistochemistry analysis. **RESULTS:** In the IAE model, MY10 reduced ethanol intake only in male mice. This MY10 effect was not accompanied by significant alterations in glial responses. In acute ethanol experiments, ethanol did not alter microgliosis significantly. However, female mice showed a more activated microglia phenotype independently of the treatment received. In the hippocampus, MY10 prevented ethanol-induced neurogenic loss in both male and female mice, without significant effects on glial responses. **CONCLUSION:** RPTPβ/ζ inhibition significantly reduced chronic ethanol consumption only in male mice. RPTPβ/ζ critically modulates ethanol-induced decreases on hippocampal neurogenesis. The data also showed sex differences in RPTPβ/ζ function relevant to ethanol-induced neuroimmune responses. Funding: National Plan on Drug abuse, Ministerio de Sanidad of Spain (MSSSI, grant PNSD015I2019 to G.H.).

Role of RPTPβ/ζ in neuroinflammation and microglia-neuron communication.
Pleiotrophin (PTN) is a cytokine that is upregulated in different neuroinflammatory disorders. Using mice with transgenic PTN overexpression in the brain (Ptn-Tg), we have found a positive correlation between iNos and Tnfα mRNA and Ptn mRNA levels in the prefrontal cortex (PFC) of LPS-treated mice. PTN is an inhibitor of Receptor Protein Tyrosine Phosphatase (RPTP) β/ζ, which is mainly expressed in the central nervous system. We aimed to test if RPTPβ/ζ is involved in the modulation of neuroinflammatory responses using specific inhibitors of RPTPβ/ζ (MY10 and MY33-3). Treatment with MY10 potentiated LPS-induced microglial responses in the mouse PFC. Surprisingly, MY10 caused a decrease in LPS-induced NF-κB p65 expression, suggesting that RPTPβ/ζ may be involved in a novel mechanism of potentiation of microglial activation independent of the NF-κB p65 pathway. MY33-3 and MY10 limited LPS-induced nitrites production and iNos increases in BV2 microglial cells. SH-SY5Y neuronal cells were treated with the conditioned media from MY10/LPS-treated BV2 cells. Conditioned media from non-stimulated and from LPS-stimulated BV2 cells increased the viability of SH-SY5Y cultures. RPTPβ/ζ inhibition in microglial cells disrupted this neurotrophic effect of microglia, suggesting that RPTPβ/ζ plays a role in the neurotrophic phenotype of microglia and in microglia-neuron communication.

Although it is known that early life stress is a risk factor for developing an Alcohol, Use Disorders (AUD), the underlying neurobiological mechanisms are not fully understood. Maternal separation stress (MS) is a predictive animal model to evaluate the effects of early stress exposure on alcohol intake. We aimed to investigate the influence of MS on alcohol consumption and stress responses of adult male and female mice. C57BL/6J mice were subjected to 180 min of MS, from the postnatal day (PND) 1 to 14, or were left undisturbed in their home-cage (control). On PND 45, mice were individually exposed to 20% alcohol (w/v) in filtered water, in their home cages for 3 weeks (involuntary consumption). Next, mice were trained to self-administrate alcohol in an operant procedure under fixed ratio (FR 1-3-5), 120-min sessions. The “breakpoint” was determined in 3 two-hour sessions of a progressive ratio schedule. Next day, mice were submitted or not to Rat Exposure Test (RET) and 24h later, they had free access to alcohol 20% during 4h (binge). Blood samples were collected before alcohol protocol begin (basal), after the RET, and after the binge session. In involuntary consumption, female mice increased ethanol intake compared to male mice. Female MS mice and control male mice submitted to RET presented higher blood corticosterone concentrations when compared to female control group. Maternal separation stress seems to influence stress responses to an acute heterotypic stressor exposure in a sex-dependent manner in adult mice. Grant: CAPES, FAPESP, UNIFESP

A ROLE FOR THE BDNF SYSTEM IN THE ACTIVITY-BASED ANOREXIA RAT MODEL: FOCUS ON THE AMYGDALA

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Francesca Mottarlini, Giorgia Targa, Beatrice Rizzi, Fabio Fumagalli, Lucia Caffino
Università degli Studi di Milano, Department Of Pharmacological And Biomolecular Sciences, Milan, Italy

Anorexia nervosa (AN) is one of the most severe psychiatric disorders whose rate of incidence is worrying, especially among adolescents. AN patients suffer from a pathological fear of gaining weight, altered body-shape perception, and emotional instability. Our hypothesis is that neuroplastic alterations in the amygdala, a brain region involved in the regulation of emotional processes, might be associated with the maintenance of the anorexic phenotype. In particular, we focused the role of the neurotrophin BDNF in the amygdala of adolescent female rats exposed to the Activity-Based Anorexia (ABA) protocol, characterized by the culprits of AN: the combination of caloric restriction and intense physical exercise. Twenty-four hours after the anorexic phenotype induction, ABA animals reduce body weight and exponentially increase wheel activity over days. At molecular level, despite ABA rats show increased total Bdnf, Bdnf isoform IV and VI gene expression in the acute phase of the disease (post-natal day [P]42), protein levels of BDNF, its receptor TrkB and its downstream signaling pathway, i.e. Akt and Erk2, are reduced in the membrane fraction. Interestingly, this overall reduction in the BDNF system persists following 7 days of body weight recovery (P49). Taken together, these data suggest that the combination between hyperactivity and reduced caloric intake alters the trophic support and neuroplastic mechanisms in the amygdala, via BDNF system dysregulation, an effect that might be crucial in the onset of comorbid complications in AN patients and, thus, increase the vulnerability to develop other psychiatric disorders. Single Exposure to the Cathinones MDPV and α-PVP Alters Molecular Markers of Neuroplasticity in the Adult Mouse Brain.
Synthetic cathinones have gained popularity among young drug users and are widely used in the clandestine market. While the cathinone-induced behavioral profile has been extensively investigated, information on their neuroplastic effects is still rather fragmentary. Accordingly, we have exposed male mice to a single injection of MDPV and α-PVP and sacrificed the animals at different time points (i.e., 30 min, 2 h, and 24 h) to have a rapid readout of the effect of these psychostimulants on neuroplasticity in the frontal lobe and hippocampus, two reward-related brain regions. We found that a single, low dose of MDPV or α-PVP is sufficient to alter the expression of neuroplastic markers in the adult mouse brain. In particular, we found increased expression of the transcription factor , increased ratio between the vesicular GABA transporter and the vesicular glutamate transporter together with changes in the expression of the neurotrophin , confirming the widespread impact of these cathinones on brain plasticity. To sum up, exposure to low dose of cathinones can impair cortical and hippocampal homeostasis, suggesting that abuse of these cathinones at much higher doses, as it occurs in humans, could have an even more profound impact on neuroplasticity.

Metaplastic Effects of Ketamine and MK-801 on Glutamate Receptors Expression in Rat Medial Prefrontal Cortex and Hippocampus.
Ketamine and MK-801 by blocking NMDA receptors may induce reinforcing effects as well as schizophrenia-like symptoms. Recent results showed that ketamine can also effectively reverse depressive signs in patients' refractory to standard therapies. This evidence clearly points to the need of characterization of effects of these NMDARs antagonists on relevant brain areas for mood disorders. The aim of the present study was to investigate the molecular changes occurring at glutamatergic synapses 24 h after ketamine or MK-801 treatment in the rat medial prefrontal cortex (mPFC) and hippocampus (Hipp). In particular, we analyzed the levels of the glutamate transporter-1 (GLT-1), NMDA receptors, AMPA receptors subunits, and related scaffolding proteins. In the homogenate, we found a general decrease of protein levels, whereas their changes in the post-synaptic density were more complex. In fact, ketamine in the mPFC decreased the level of GLT-1 and increased the level of GluN2B, GluA1, GluA2, and scaffolding proteins, likely indicating a pattern of enhanced excitability. On the other hand, MK-801 only induced sparse changes with apparently no correlation to functional modification. Differently from mPFC, in Hipp, both substances reduced or caused no changes of glutamate receptors and scaffolding proteins expression. Ketamine decreased NMDA receptors while increased AMPA receptors subunit ratios, an effect indicative of permissive metaplastic modulation; conversely, MK-801 only decreased the latter, possibly representing a blockade of further synaptic plasticity. Taken together, these findings indicate a fine tuning of glutamatergic synapses by ketamine compared to MK-801 both in the mPFC and Hipp.

Repeated exposure to cocaine during adolescence enhances the rewarding threshold for cocaine-conditioned place preference in adulthood.
Previous studies have shown that adolescent exposure to cocaine increases drug use in adulthood, albeit incubation of cocaine seeking was found to be attenuated in rats trained to self-administer cocaine during adolescence. We here hypothesize that adolescent exposure to cocaine could alter the rewarding properties of the psychostimulant in adulthood. By employing two of the most widely used animal-experimental-preclinical models to investigate drug addiction, we evaluated whether contingent versus non-contingent cocaine self-administration during adolescence modulates its rewarding threshold in adulthood evaluated by conditioned place preference (CPP). Cocaine self-administration during adolescence increases the rewarding threshold in adulthood; CPP for cocaine was observed at the higher (20 mg/kg), but not at the lower (10 mg/kg), dose employed. Rats exposed to either contingent or non-contingent cocaine during adolescence exhibited the same behavior in the CPP paradigm suggesting that, under our experimental conditions, cocaine rewarding properties are shaped by the psychostimulant itself and not by its motivational effects. From a mechanistic standpoint, the preference for the 20 mg/kg cocaine-paired side in a CPP paradigm appears to depend, at least partially, upon the formation of GluA2-lacking Ca -permeable AMPA receptors and the consequent increase of αCaMKII activity in the NAc, both of which are instead reduced when the 10 mg/kg dose was used. In conclusion, contingent or non-contingent cocaine exposure during adolescence desensitizes adult animals to a rewarding dose of cocaine (10 mg/kg) elevating the rewarding threshold necessary (20 mg/kg) to drive conditioned place preference, an effect that may predispose to higher consumption of cocaine during adulthood.

Activity-Based Anorexia Dynamically Dysregulates the Glutamatergic Synapse in the Nucleus Accumbens of Female Adolescent Rats.
Intense physical activity and dieting are core symptoms of anorexia nervosa (AN). Their combination evolves into compulsivity, leading the patient into an out-of-control spiral. AN patients exhibit an altered activation of nucleus accumbens (NAc), revealing a dysfunctional mesocorticolimbic reward circuitry in AN. Since evidence exists that a dysregulation of the glutamate system in the NAc influences reward and taking advantage of the activity-based anorexia (ABA) rat model, which closely mimics the hallmarks of AN, we investigated the involvement of the glutamatergic signaling in the NAc in this experimental model. We here demonstrate that food restriction causes hyperactive and compulsive behavior in rodents, inducing an escalation of physical activity, which results in dramatic weight loss. Analysis of the glutamate system revealed that, in the acute phase of the pathology, ABA rats increased the membrane expression of GluA1 AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptor subunits together with its scaffolding protein SAP97. Recovery of body weight reduced GluN2A/2B balance together with the expression of their specific scaffolding proteins, thus suggesting persistent maladaptive neurotransmission. Taken together, AMPA and NMDA (N-methyl-D-aspartate) receptor subunit reorganization may play a role in the motivational mechanisms underlying AN.

Anhedonic-like behavior and BDNF dysregulation following a single injection of cocaine during adolescence.
We have previously demonstrated that a single exposure to cocaine during adolescence causes several behavioural and neurobiological changes, highlighting the unique vulnerability of this period of life. The purpose of our work was to investigate whether a single exposure to cocaine during brain development is sufficient to shape a negative emotional state in adolescent rats. A single injection of cocaine during adolescence followed by measurement of sucrose consumption, a measure of anhedonia, identifies two separate groups of rats, i.e. anhedonic (AN) and non anhedonic (NON-AN) rats. AN rats show reduced ability to synthesize, traffic and translate the neurotrophin BDNF at synaptic level, reduced activation of hippocampal BDNF signaling, reduced BDNF plasma levels and a steep rise of corticosterone secretion. Conversely, NON-AN rats exhibit reduced trafficking of BDNF while up-regulating hippocampal BDNF synthesis and stabilizing its downstream signaling with no changes of BDNF and corticosterone plasma levels. Adult rats exposed to cocaine showed no signs of anhedonia, an increase of BDNF both in hippocampus and plasma and decreased levels of corticosterone. In conclusion, our findings reveal a complex central and peripheral dysregulation of BDNF-related mechanisms that instead are preserved in NON-AN rats, suggesting that BDNF modulation dictates behavioural vulnerability vs. resiliency to cocaine-induced anhedonia, a profile uniquely restricted to adolescent rats.

Repeated cocaine exposure during adolescence impairs recognition memory in early adulthood: A role for BDNF signaling in the perirhinal cortex.
The perirhinal cortex (PrhC) is critical for object recognition memory; however, information regarding the molecular mechanisms underlying this type of memory following repeated exposure to drugs of abuse during adolescence is unknown. To this end, adolescent or adult rats were exposed to cocaine from postnatal day (PND) 28 to PND 42 or PND 63 to PND 77, respectively. Two weeks later, rats were subjected to the cognitive test named Novel Object Recognition (NOR) test. We found that adolescent, but not adult, cocaine exposure caused a significant impairment in the NOR test, independently from changes in the stress response system. In adolescent saline-treated rats, NOR test up-regulated BDNF and its downstream signaling whereas a downregulation of the same pathway was observed in cocaine-treated rats together with a reduction of Arc/Arg3.1 and PSD95 expression, indicating reduced pro-cognitive structural adaptations in the PrhC. Of note, cocaine-treated adult rats correctly performed in the NOR test indicating intact recognition memory mechanisms, despite a significant cocaine-induced reduction of BDNF levels in the PrhC, suggesting that recognition memory is heavily dependent on BDNF during adolescence whereas during adulthood other mechanisms come into play.

The role of the serotonin transporter in prefrontal cortex glutamatergic signaling following short- and long-access cocaine self-administration.
Vulnerability to drug addiction relies on substantial individual differences. We previously demonstrated that serotonin transporter knockout (SERT) rats show increased cocaine intake and develop signs of compulsivity. However, the underlying neural mechanisms are not fully understood. Given the pivotal role of glutamate and prefrontal cortex in cocaine-seeking behavior, we sought to investigate the expression of proteins implicated in glutamate neurotransmission in the prefrontal cortex of naïve and cocaine-exposed rats lacking SERT. We focused on the infralimbic (ILc) and prelimbic (PLc) cortices, which are theorized to exert opposing effects on the control over subcortical brain areas. SERT rats, which compared to wild-type (SERT) rats show increased ShA and LgA intake short-access (ShA) and long-access (LgA) cocaine intake, were sacrificed 24 h into withdrawal for ex vivo molecular analyses. In the ILc homogenate of SERT rats, we observed a sharp increase in glial glutamate transporter 1 (GLT-1) after ShA, but not LgA, cocaine intake. This was paralleled by ShA-induced increases in GluN1, GluN2A, and GluN2B NMDA receptor subunits and their scaffolding protein SAP102 in the ILc homogenate, but not postsynaptic density, of these knockout animals. In the PLc, we found no major changes in the homogenate; conversely, the expression of GluN1 and GluN2A NMDA receptor subunits was increased in the postsynaptic density under ShA conditions and reduced under LgA conditions. These results point to SERT as a critical regulator of glutamate homeostasis in a way that differs between the subregions investigated, the duration of cocaine exposure as well as the cellular compartment analyzed.

Deletion of the serotonin transporter perturbs BDNF signaling in the central amygdala following long-access cocaine self-administration.
Human neuroimaging studies indicate that the amygdala plays a key role in cocaine addiction. One key plasticity factor that

modulates effects of cocaine on the brain is Brain-Derived Neurotrophic Factor (BDNF). A wealth of evidence shows that cocaine exposure alters BDNF signaling in corticolimbic structures, but, surprisingly, such evidence is very limited for the amygdala. Additionally, while BDNF is strongly regulated by serotonin levels and inherited serotonin transporter down-regulation is associated with increased vulnerability to cocaine addiction, the effects of serotonin transporter genotype on BDNF signaling in the amygdala under naïve and cocaine exposure conditions are unknown.

Anorexia nervosa (AN) is a complex mental illness characterized by restricted eating and strenuous exercise regimens. Our major aim was to investigate the molecular and structural signature of AN history on stress-related mechanisms in the hippocampus of the activity-based anorexia (ABA) rat model, a well-established animal model of AN,in mediating the hallmarks of the anorexic phenotype. Following exposure of female adolescent rats to the combination of food restriction and physical activity (i.e. the ABA protocol), ABA rats show reduced body weight and increased wheel activity over days. ABA rats alter their pattern of activity over days showing increased food anticipatory activity, a readout of their motivation to engage in intense physical activity.Corticosterone levels were enhanced in the plasma of ABA rats in the acute phase of the pathology (postnatal day [P]42) and reduced following 7-days recovery period at P49. At molecular level, in the membrane fraction of the hippocampus, we found reduced levels of glucocorticoid receptor together with reduced activity of phospho-synapsin1, an indirect index of reduced neurotransmitter release. Such impairment was strengthened by reduced expression of caldesmon, n-cadherin and neuroligin-1, molecular markers of cytoskeletal stability. Accordingly, structural analyses revealed reduced dendritic spine density and reduced number of mushroom-shaped spines, together with an increased number of filopodia. Notably, these effects persisted even when body weight of ABA rats was restored. This maladaptive plasticity paralleled by the reorganization of the hippocampal architecture could represent a signal of altered processing of food reward and a vulnerability trait for relapse. Disturbance in synaptic excitatory and inhibitory (E/I) transmission in the prefrontal cortex has been considered as a critical factor for cognitive dysfunction, a core clinical symptom in schizophrenia. However, the systematic study of E/I imbalance caused cortical network pathophysiology, as well as the effective therapeutic strategy, is still limited. In this study, we used mice with parvalbumin neuron (PV) specific knockout of GluA1 (AMPA receptor subunit 1) (Gria1-PV KO) as an experimental tool to study PV loss of function-mediated network disruption. With high-content confocal imaging and electrophysiological recordings in the medial prefrontal cortical (mPFC) section, we found the structural and functional alteration in mPFC local network of Gria1-PV KO. In addition, we applied electroencephalography (EEG) and mismatch negativity (MMN) test, standard tools in the clinic for measuring network activity and sensory information processing. Gria1-PV KO animals exhibited abnormal theta oscillation and deficit in the MMN comparable to clinical findings from cognitive impairment patients. Remarkably, we demonstrate that application of glycine transporter inhibitor 1 (GlyT1) inhibitor, bitopertin, ameliorated imbalanced E/I transmission, hyperexcitability, and sensory processing malfunction from Gria1-PV KO. Therefore, our results suggest that PV-specific deletion of GluA1 is an experimental approach for back-translating the E/I imbalance observed in schizophrenic patients. Additionally, our work offers a systematic workflow to understand the effect of bitopertin in restoring cortical network activity from single cell to local brain circuitry. Furthermore, this study highlights that increasing excitatory drive through boosting NMDA receptor signaling pathways is a potential therapeutic strategy for restoring E/I imbalance-mediated cognitive abnormality.

GESTATIONAL STRESS INDUCES MITOCHONDRIAL DYSFUNCTION IN PREFRONTAL CORTEX AND DEPRESSIVE-LIKE BEHAVIOR IN POSTPARTUM RATS

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Erin Gorman-Sandler, Jesseca Crawford, Breanna Robertson, Fiona Hollis
University of South Carolina School of Medicine, Pharmacology, Physiology, And Neuroscience, Columbia, United States of America

Postpartum depression (PPD) is a major psychiatric complication of childbirth, affecting up to 20% of mothers, yet remains understudied. Proposed mechanisms underlying PPD pathology share a link with mitochondria-- dynamic organelles crucial for cell homeostasis. The brain relies on mitochondrial energy production to function, and stress, a major risk factor for PPD, amplifies brain energy demands. In turn, brain mitochondrial function is also affected by stress and linked to anxiety-like and social behaviors. Consequently, failure to properly adapt to the demands of stress could increase the risk for psychiatric illness. Considering the importance of mitochondria in regulating brain function and behavior, we hypothesized a role for mitochondrial dysfunction in association with behavioral changes in a chronic stress-induced rat model of PPD. Adult female Wistar rats were separated into nulliparous controls (C), stressed (S), and primiparous controls (P), and stressed (P+S) groups. P+S and S groups were exposed to chronic mild unpredictable stress for 10 days during the P+S late gestational period. Anhedonia and stress-coping behaviors measured in the early postpartum period were increased in P+S rats, while anxiety-like behavior was unaffected. On postpartum day 11, ex vivo mitochondrial function measured in prefrontal cortex (PFC) was decreased by gestational stress, while nucleus accumbens (NAc) respiration was unaffected. Levels of pro-inflammatory cytokines in plasma and PFC indicated a heightened proinflammatory profile in P+S and S rats. Overall, we report an association between PFC mitochondrial respiration and PPD-like behaviors following gestational stress, with a potential role for inflammatory signaling.

Background: Antidepressants have been proposed to act by binding to TrkB receptors which facilitates BDNF-induced activation of TrkB and synaptic plasticity. However, our findings demonstrate that some antidepressants, most notably nitrous oxide (N_2O), trigger TrkB signaling only after their acute pharmacological effects dissipate, during a state resembling deep sleep or sedation. Indeed, not only antidepressants but also a wide range of tested sedatives readily activate TrkB. **Aims:** To investigate physiological characteristics associated with drug-induced TrkB activation, and to test whether TrkB activation can be manipulated by disrupting such physiological alterations. **Methods:** Time-dependent effects of N_2O on locomotor behavior, EEG (electroencephalogram), body temperature, brain glucose utilization, and brain TrkB signaling were studied in adult mice. Next, we investigated the acute effects of sedatives (e.g. medetomidine) and sedative antidepressants (incl. amitriptyline) on TrkB signaling and body temperature. Finally, we tested the intriguing possibility that the effects of amitriptyline on TrkB signaling can be abolished by simply maintaining animal´s body temperature. **Results/Conclusions:** TrkB signaling and several characteristic features associated with deep sleep were evoked after cessation of N_2O administration: slow-wave EEG activity, behavioral immobility, reduced brain glucose utilization and hypothermia. Various sedatives and sedative antidepressants activated TrkB, and this was accompanied by reduced body temperature. Maintaining animals normothermic, supressed amitriptyline-induced TrkB signaling. These results suggest that TrkB activation is triggered by an evoked physiological response, rather than direct receptor binding, connected to drugs ability to reduce energy expenditure and consequently, body temperature. This study links bioenergetics and thermoregulation into the effects of antidepressants.

DOSE-DEPENDENT EFFECTS OF KETAMINE ON ELECTROPHYSIOLOGICAL NETWORK ACTIVITY AND TRKB-ERK SIGNALING IN CORTICAL NEURONAL CULTURE

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Iina Annala[1], Annika Ahtiainen[2], Marko Rosenholm[3], Samuel Kohtala[4], Jarno Tanskanen[2], Jari Hyttinen[2], Tomi Rantamäki[1]

Background:
Subanesthetic-dose ketamine increases glutamatergic neuronal activity in the cortex. This effect has been proposed to facilitate BDNF (brain-derived neurotrophic factor) release and activation of TrkB receptor and extracellular signal-regulated kinase (ERK) signaling. Previous data suggests that ketamine dose-dependently regulates ERK signaling also in cortical neuron cultures, but effects on TrkB and neuronal network activity remain unclear. Aims: To characterize spontaneous network activity and responses to BDNF on primary neuronal cultures during different maturational stages. To examine the effects of carbachol, diazepam and different doses of ketamine (100nM - 10µM) on electrophysiological network activity and TrkB-ERK signaling in cultures which are readily responsive to BDNF. Methods: Rat E18 cortical cells were cultured on microelectrode arrays (12 electrodes/well) and spontaneous network activity was followed for 5 weeks. Acute electrophysiological responses to BDNF and drugs were recorded after 14 or 35 days in vitro (DIV). After stimulation, cells were lysed and TrkB/ERK phosphorylation analyzed using western blotting. Results/conclusions:
Spontaneous spiking and bursting steadily increased during DIV5-21 but declined towards DIV35. BDNF robustly increased phosphorylation of TrkB and ERK at DIV14 while a more marginal response was seen at DIV35. Hence, effects of drugs were investigated at DIV14. Diazepam (10 µM) abolished electrical activity and reduced p-ERK, while carbachol (25 µM) caused variable increases in activity and did not affect p-ERK. Ketamine (100-500 nM) caused dose-dependent decreases on spiking/bursting, with 500 nM showing a significant decrease without change in p-ERK. Ketamine (10 µM) strongly reduced spiking, bursting and p-ERK. None of the drug treatments influenced p-TrkB.

Major depressive disorder (MDD) is recognized as a major source of disability and mortality worldwide. Current therapeutic treatments are effective in only half of patients. In-depth understanding of treatments and discovering novel ones have been lagged due to a huge gap in the development of an appropriate disease model. Here, we generated neurons from human induced pluripotent stem cells (hiPSCs) to serve as a starting point to develop a human model, and to test an experimental drug NitroSynapsin (NS), to translate results from animals into human. Chronic restrain stress (CRS) animal model was employed to mimic depressive-like behaviour. Thereafter, all animals were subjected to the sucrose preference (SPT) and tail suspension tests (TST). Subchronic treatment of NS reversed behavioural disturbances induced by CRS in regard to SPT and TST. NS also reversed changes in morphology and density of dendritic spines, observed in cortical neurons of CRS animals. To confirm if the findings in animals would be similar in humans, hiPSCs were differentiated into Nestin+ and Pax6+ neural progenitor cells (NPCs). NPCs were differentiated into neural precursors which gave rise to βIII-Tubulin+, MAP2+ neurons under further maturation. Spine-like protrusions could be observed in neurons undergoing 1-month maturation. Matured iPSC-neurons (≥6 weeks in vitro) will be stressed by cortisol and treated by NS so as to assess the effect. In summary, we have observed that NS improved behaviours in CRS mice model and restored the morphology and density of dendritic spines. Our further work aims at translating these findings into hiPSC-derived neurons.

Oleanolic acid enhances neural stem cell migration, proliferation, and differentiation in vitro by inhibiting GSK3β activity. Oleanolic acid (OA), one of the bioactive ingredients in ginseng, has been reported to have neuroprotective activities. However, the effects and its mechanism on neural stem cell (NSC) induction are not entirely clear. In the present study, we investigated the effects of OA on promoting the migration, proliferation, and differentiation of neural stem cells (NSCs). Migration and proliferation were investigated by using neural-specific markers, neurosphere assay, and Cell Counting Kit-8, respectively. We found OA remarkably promoted neural migration and proliferation of NSCs in a time- and dose-dependent manner. Differentiation was analyzed by western blotting and immunofluorescence staining, which found MAP2 expression was remarkably increased, whereas Nestin was dramatically decreased. In addition, OA increased phosphorylation of GSK3β at Ser9 and expression of active forms of β-catenin. Furthermore, NSCs with constitutively active GSK3β (S9A) significantly suppressed the OA-induced proliferation and neural differentiation. These results showed that OA could stimulate NSC proliferation and neural differentiation in vitro via suppressing the activity of GSK3β. Our findings may have significant implications for the treatment of neurodegenerative diseases.

Our laboratory has previously demonstrated that adolescent binge drinking affects CB1 receptor expression in the excitatory medial perforant path (MPP) synaptic terminals of the adult mouse hippocampus that associates with loss of endocannabinoid-dependent synaptic plasticity at the MPP and memory impairment. Strong evidences have shown that omega-3 prevents neurodegeneration and oxidative stress caused by adult EtOH exposure. Thus, omega-3 might promote recovery from the long-term damage caused by binge drinking during adolescence. To investigate this, 4 week-old C57BL/6J male mice were exposed to a drinking-in-the-dark procedure from PND 32 to 59 (H2O, EtOH). During withdrawal (PND 60-73), one half had omega-3-enriched diet (EPA 2.7% and DHA 2%) (O3-H2O, O3-EtOH). Then, learning, memory, motor performance and anxiety were assessed by the Barnes maze, novel object recognition, beam walking, rotarod and anxiety behavioral tests. Also, immunohistochemistry and western blotting were performed in the hippocampus. Omega-3 ameliorated cognitive and motor deficits after adolescent binge drinking. In addition, omega-3 treated groups were less anxious and had better recognition memory. This cognitive and behavioral improvement correlated with a drastic reduction in MGL optical density and synaptosomal DGLα as well as with a remarkable CRIP-1a increase, relative to EtOH. Furthermore, CB1 receptor expression in whole hippocampal synaptosomes was significantly higher in EtOH and O3-EtOH than in H2O. Taken together, these results indicate that omega-3 intake impacts on components of the endocannabinoid system and has concurrent beneficial effects on behavior in adult mice after binge drinking during adolescence.

SIMULATED MICROGRAVITY REMODELS THE NEUROCHEMISTRY OF MONOAMINERGIC SYSTEMS ACROSS THE RAT BRAIN

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Leandre Lavenu, Alexandra Gros, Jean-Luc Morel, Philippe De Deurwaerdère
Université de Bordeaux, Cnrs, Incia, Umr 5287, Bordeaux, France

Aims Spaceflights are challenging for astronauts for decision making, movement adaptation, and vestibular control. Monoaminergic systems regulate those adaptive functions and could play a role in some maladaptive responses during spaceflight and upon the return to earth. The goal of our study was to explore the neurochemistry of dopaminergic, noradrenergic and serotonergic systems alone and in interaction each other in a rodent model of simulated microgravity (hindlimb unloading suspension). Methods To simulate microgravity, male Long-Evans rats were hindlimb suspended during 7 days. Rats were euthanized, brains frozen, and 30 cortical and subcortical structures involved in cognitive, motor and mood functions were extracted. Those were measured for monoamines and their metabolites contents by High Pressure Liquid Chromatography coupled to electrochemical detection. Results Simulated microgravity altered the tissue levels of dopamine and noradrenaline along some structures of the vestibular/motor systems (red nucleus, substantia nigra, inferior olive, and cerebellum). A reduction of dopamine neurochemical markers was observed in the shell of the nucleus accumbens, and, together with serotonin, in the prelimbic cortex. Spermann's correlations revealed important variations of serotonergic network between brain regions alone and in relation with dopamine. Conclusion Our study suggests that quantitative catecholamine's distribution in the vestibular/motor systems, as well as dopamine and serotonin in the prelimbic cortex are notably affected by simulated microgravity exposure. Remodeling of the serotonergic function could represent an adaptive response to microgravity, perhaps at the expenses of adaptive responses upon the return to earth conditions.

IMPAIRED COGNITION AND BEHAVIOR ASSOCIATE WITH CHANGES IN THE BRAIN ENDOCANNABINOID-DEPENDENT SYNAPTIC PLASTICITY OF ADULT FEMALE MICE AFTER BINGE DRINKING DURING ADOLESCENCE

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Recent work in our laboratory has shown the lack of cannabinoid-dependent hippocampal synaptic plasticity in adult male mice after binge drinking during the adolescence. However, the brain consequences of similar alcohol intake pattern in adolescent females are still controversial. To investigate this, female C57BL/6J adolescent mice (pnd32 to pnd56) were exposed to drinking-in-the-dark procedure followed by two weeks of withdrawal. During the last abstinence days, anxiety-like behavior, learning and memory and motor coordination were assessed. In addition, hippocampal synaptic plasticity and expression of some components of the endocannabinoid system were analyzed. Adolescent females consumed 50% more alcohol than males. Moreover, females in the adulthood showed significantly more anxiety-like behavior and impaired motor coordination and memory after adolescent binge drinking. Although hippocampal synaptic plasticity was unaffected, excitatory long-term depression at the dentate medial perforant path synapses was cannabinoid CB1 receptor independent in adult females exposed to EtOH in the adolescence. No differences were found in the expression of synaptosomal CB1, DGLα, PLCβ1 and Crip1a between hippocampi of controls and EtOH, but Crip1a was significantly increased in both EtOH and control females versus males. In conclusion, adolescent binge drinking impairs cognition, motor behavior and mood as well as alters the cannabinoid molecular mechanisms of synaptic plasticity in adult female mice. Noticeably, these changes do not correlate with modifications in at least some main components of the endocannabinoid system.

Cognitive and neurobehavioral benefits of an enriched environment on young adult mice after chronic ethanol consumption during adolescence.
Binge drinking (BD) is a common pattern of ethanol (EtOH) consumption by adolescents. The brain effects of the acute EtOH exposure are well-studied; however, the long-lasting cognitive and neurobehavioral consequences of BD during adolescence are only beginning to be elucidated. Environmental enrichment (EE) has long been known for its benefits on the brain and may serve as a potential supportive therapy following EtOH exposure. In this study, we hypothesized that EE may have potential benefits on the cognitive deficits associated with BD EtOH consumption. Four-week-old C57BL/6J male mice were exposed to EtOH following an intermittent 4-day drinking-in-the-dark procedure for 4 weeks. Then they were exposed to EE during EtOH withdrawal for 2 weeks followed by a behavioral battery of tests including novel object recognition, novel location, object-in-place, rotarod, beam walking balance, tail suspension, light-dark box and open field that were run during early adulthood. Young adult mice exposed to EE significantly recovered recognition, spatial and associative memory as well as motor coordination skills and balance that were significantly impaired after adolescent EtOH drinking with respect to controls. No significant permanent anxiety or depressive-like behaviors were observed. Taken together, an EE exerts positive effects on the long-term negative cognitive deficits as a result of EtOH consumption during adolescence.

Psychiatric disorders are complex neurodevelopmental conditions, which can be explained partly by a genetic component as well as by environmental factors. Recent epidemiological studies have suggested that post-natal and peri-natal exposure to air pollution could play a role in the development of several psychiatric disorders, in particular for those living in areas where the concentration of pollutants exceeds the limits set by the World Health Organization. However further research needs to be done to demonstrate a direct impact of air pollution as well as to understand the biological mechanisms involved. Here, we investigated the impact of a prenatal exposure to a realistically simulated air pollution of Paris and Beijing during a critical phase of brain development, the last third of gestation. We compared social interactions, anxiety and anhedonia in the offspring of exposed and not exposed animals at three periods of life, i.e. childhood (6 days post-natal), early adolescence (30 days post-natal), and adulthood (over 90 days post-natal). In parallel, we compared the gene expression in the prefrontal cortex of exposed and not exposed mice at the early adolescence and adulthood. We reported alteration of ultrasonic vocalization in pups and modification of social behavior in adolescence and adulthood for exposed animals. We also identified genes that were differentially expressed between exposed and not exposed animals with an enrichment in gene expression regulation and immune signaling. Altogether, our results suggest that prenatal exposure to air pollutants may affect brain functioning and behaviors of the offspring.

PREFRONTAL INHIBITORY CIRCUITS ARE IMPACTED BY CHRONIC STRESS AND DRIVE STRESS-ASSOCIATED BEHAVIORAL IMPAIRMENTS

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Juan Santoyo, Raju, Davison, Milman, Abdelaal, Liu, Li-Huei Tsai
Massachusetts Institute of Technology, Brain And Cognitive Sciences, Boston, United States of America

Prefrontal cortical circuits and prefrontal inhibitory circuits in particular are thought to be impacted by adverse events and chronic stress. These circuit impacts may underlie clinical observations that adverse events and stress may impair normal cognition and perseverate psychiatric disorders like schizophrenia, bipolar disorder, major depression, and anxiety. In this study we aim to assess how chronic stress drives changes in mouse inhibitory circuits and impacts behaviors associated with executive function, anxiety, and social behavior. To do this, we use a validated mouse model for chronic stress, the limited nesting and bedding (LNB) model, in which mice are reared in resource-deprived conditions starting at postnatal day 2. In this model, mice express impacts to behaviors associated with prefrontal dysfunction and we have quantified a reduction in prefrontal parvalbulmin interneurons in adulthood. To extend this work we use RNAscope to further quantify changes in the expression of molecular markers associated with the different subtypes of cortical interneurons and demonstrate how expression levels differ between LNB and normally housed mice in prefrontal cortex, amygdala, hypothalamus, and thalamus. Since interneurons also play a role in cortical rhythms, we use skull EEG recordings from prefrontal, somatosensory, and visual cortex to demonstrate various differences in frequency specific activity and in sleep-associated cortical rhythms between groups. Finally, we use optogenetic stimulation of prelimibic pravalbumin-positive interneurons in order to rescue some of the behaviors impacted in LNB mice, suggesting that this circuit impairment may underlie some of the disease associated impairments that result from chronic stress.

A PRIMATE SUBCALLOSAL CINGULATE AREA 25 NETWORK FRACTIONATES ANHEDONIA, ANXIETY AND RAPID ANTIDEPRESSANT RESPONSE

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Christian Wood[1], Laith Alexander[2], Johan Alsiö[3], Andrea Santangelo[1], Lauren Mciver[1], Gemma Cockcroft[1], Angela Roberts[4]
[1]University of Cambridge, Physiology, Development And Neuroscience, Cambridge, United Kingdom, [2]King's College London, Institute Of Psychiatry, Psychology And Neuroscience, London, United Kingdom, [3]University of Cambridge, Department Of Psychology, Cambridge, United Kingdom, [4]University of Cambridge, Department Of Physiology, Development And Neuroscience, Cambridge, United Kingdom

Understanding the dysregulated circuits that underlie the symptoms and treatment response in anxiety and depression are critical for developing more effective therapies. Patients show elevated subcallosal cingulate cortex activity (scACC) and recent studies in primates revealed its causal contribution to both anhedonia and anxiety and its sensitivity to ketamine. The current study sought to fractionate the area 25 networks underlying these effects.

In marmosets, excitatory DREADDs were expressed in scACC area 25 output neurons (scACC-25; AAV8-CaMKIIa-HA-hM3Dq) and specific pathways activated by intracerebral infusion of Clozapine-N-Oxide (CNO, 3uM) into terminals within the nucleus accumbens (scACC-25>NAcc) and amygdala (scACC-25>Amyg) prior to appetitive and threat-related paradigms (n=3-5). Reward anticipation was studied using appetitive Pavlovian conditioning where two sounds predict, respectively, food access or not (conditioned stimuli, CS+/-). Uncertain threat reactivity was assessed by the human intruder test (HI-Test) whereby a novel human faces the marmoset for two minutes; with the multifaceted behaviours combined into an anxiety-like score. Amelioration of reward deficits induced by systemic CNO-mediated scACC-25 activation were studied via intra-accumbens ketamine infusions.

ScACC-25>NAcc activation blunted anticipatory CS+ arousal, whilst scACC-25>Amyg activation had no effect (Treatment*Region*CS, p=0.011; CS+ scACC-25>NAcc Veh/CNO, p=0.046). In contrast, only scACC-25>Amyg activation heightened threat reactivity in the HI-Test (Treatment*Region, p=0.011; scACC-25>Amyg Veh/CNO, p=0.002). Intra-accumbens ketamine blocked the blunting of anticipatory arousal by systemic CNO treatment (Treatment*CS, p=0.005; CS+ Saline/Ketamine, p=0.014).

Together, these data indicate circuit-specificity with scACC-25 overactivity inducing anhedonia-like and anxiety-like symptomatology through distinct pathways, with the nucleus accumbens a key region for ketamine’s ameliorative effects on anhedonia.

THE INFLUENCE OF PARENTAL SOCIAL EXPERIENCE ON OFFSPRING NOVELTY-EXPLORING AND DEPRESSION-LIKE BEHAVIOR

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Milica Potrebić, Željko Pavković, Vesna Pešić
Institute for Biological Research "Siniša Stanković", National Institute of Republic of Serbia, University of Belgrade, Department Of Neurobiology, Belgrade, Serbia

Aims: The influence of parental social experience on the offspring neurodevelopment and its own susceptibility to the sculpting effect of social experience are not well understood. Using rat model we aimed to examine whether and how social experience of adolescent parents impacts psychophysical characteristics of their offspring, during pre-weaning period and later during adolescent growing in defined social conditions. **Methods:** Peripubertal Wistar rats (both sexes) were randomly selected for group housing (GH; n=3 per cage) or single housing (SH; n=1 per cage) at postnatal day (P) 29 and left undisturbed until P55. Thereafter, they were grouped for mating (SH males with SH females, GH males with GH females). Body weight (BW) of pups was monitored at P7, P14, and P21. At P17 motor activity of the offspring was monitored; at P29 the animals were subjected to GH or SH; after 1 week (P36) and 2 weeks (P43) their motor activity was monitored; at P45 they were subjected to sucrose preference test (SPT). **Results:** The male offspring of SH parents had decreased locomotor activity in a novel open arena, at P17. At P36 and P43, adolescent SH offspring showed hypolocomotion in a novel arena and hypohedonic behavior in SPT compared to GH counterparts, regardless of parental experience. BW did not differ between groups. **Conclusions:** Parental social experience influences novelty-exploring behavior of offspring, producing response below expected at P17. With further offspring development, their individual social experience has stronger impact on the appearance of depression-like phenotypes than parental social experience.

Altered hedonic, novelty-, stress- and D-amphetamine-induced response due to social isolation in peripuberty.
Reduction in direct social contact with peers during early adolescence is thought to be a risk factor for an increase in depressive symptoms, but there is still no clear evidence to suggest early behavioral manifestations and their association with the later outcome of social distancing during this period. To address this question, we used social isolation paradigm in peripubertal rats as the rodent model of adolescence. The litter was an experimental unit. On postnatal day 29, each litter gave group-housed and single-housed males, which were reared and tested one week and two weeks thereafter. Psychomotor/emotional response to novelty in exploration-based tasks, behavioral and neuronal responses to the drug reward (D-amphetamine), motivation/hedonic behavior, physiological and response to physiological stress were examined. Social isolation in peripubertal rats manifested through: hyper-reactivity/agitation and the state anxiety/risk-taking at an early stage; reduced behavioral response to D-amphetamine and altered neural processing of this stimulus, at a later stage; consummatory hypohedonia that deepened over time without changing the motivation to eat; unchanged body weight gain and resting blood corticosterone, cortisol and glucose levels over time; altered blood biochemistry (silenced corticosterone and increased glucose) due to overnight fasting only at an early stage. Our results highlight that the outcome of reduced direct social contact with peers during peripuberty is dynamic, with the cluster of atypical early symptoms that evolve into the syndrome that is delicate for assessment through routinely measurable behavior and biomarkers of stress, but with progressive consummatory hypohedonia and unaffected motivation to eat as stable marks.

Motivation, risk-taking and sensation seeking behavior in propofol anesthesia exposed peripubertal rats.
Adolescent neurodevelopment confer vulnerability to the actions of treatments that produce adaptations in neurocircuitry underlying motivation, impulsivity and reward. Considering wide usage of a sedative-hypnotic agent propofol in clinical practice, we examined whether propofol is a challenging treatment for peripubertal brain. Motivation/hedonic behavior (sucrose preference test), approach/avoidance behavior (elevated plus maze test) and response to dissociative drug phencyclidine (PCP) were studied in peripubertal rats (the rodent model of periadolescence) after propofol anesthesia

exposure (PAE). Neurodegeneration (Fluoro-Jade staining) and the expression of proteins (Western blot) involved in excitatory synaptic transmission and activity-dependent synaptic stabilization in the medial prefrontal cortex (mPFC) and striatum (components of motivation/reward circuitry; process both appetitive and aversive events) were examined as well. In peripubertal rats PAE produced 1) transient brain-region specific changes in the expression of N-methyl-d-aspartate (NMDA) receptor subunits NR2A and NR2B, PSD-95 and N-cadherin, without neurotoxicity, 2) hyperlocomotor response to PCP, 3) no changes in preference for palatable 1% sucrose solution and a decrease in food eaten, 4) preference for 20% sucrose solution without changes in food eaten, 5) stretch-attended postures and open arms entries in the elevated plus maze test. Overall, these novel findings show that PAE leaves transient synaptic trace recognized as early form of synaptic plasticity related to passive drug exposure in the brain systems implicated in motivation/reward, increases drug-responsiveness, favors risk-taking and preference of novel/intense stimuli repairing otherwise present motivational deficiency. These findings accentuate multifaceted response to propofol in peripuberty and the importance of environmental stability for the most favorable neurobehavioral recovery.

DYNAMIC HIPPOCAMPAL DNA METHYLATION TRAJECTORIES FOLLOWING IMPAIRED MATERNAL CARE

POSTER SESSION 07 - SECTION: NEUROBIOLOGY OF STRESS, ANXIETY, AND DEPRESSION

Elad Lax, Debpali Sur, Raphael Avneri, Albert Pinhasov
Ariel university, Molecular Biology, Ariel, Israel

Aims: Impaired maternal care was shown to have long-lasting effects on the adult offspring behavior through altered hippocampal DNA methylation. However, it is less clear what changes in the DNA methylation landscape occurs throughout the early postnatal developmental stages while offspring are cared by their dams.
Methods: We used mouse models of social dominance (Dom) and submissiveness (Sub), who show innate features of high and low maternal care behaviors, respectively. For genome-wide DNA methylation analysis we used reduced-representation bisulfite sequencing (RRBS-Seq) of hippocampal DNA from 7- and 21-days-old Sub and Dom pups.
Results: Sub mice showed low maternal care behaviors accompanied by reduced DNA methyltransferases expression. We found robust alterations in the DNA methylation landscape for both between-group and between timepoint analyses; with significant enrichment of differentially methylated CpGs in gene promoters encoding for genes associated with behavior, and neuronal development. Cross fostering of Sub pups with Dom dams restored many of the observed differences between Dom and Sub pups.
Conclusions: we conclude that altered methylome previously reported in the hippocampus of adult offspring of dams providing poor maternal care is perceived by early and time-dependent post-natal changes in DNA methylation patterns.

Depression is the largest contributor to disability and suicide worldwide and there is an urgent need to develop improved treatments. Conventional antidepressants can induce unpleasant and sometimes dangerous side effects, resulting in low patient compliance and a high failure response rate. *Rhodiola rosea* has traditionally been used as an adaptogen. Data from animal studies and human clinical trials suggest that it may be effective in monoamine modulation and the treatment of depressive disorders, with high tolerance and virtually no side effects, yet little is known about the mechanism of action. **Aim** The aim of this study is to determine the anti-depressant efficacy of Rhodiola *in vitro* with the potential for the treatment of mild to moderate depression. **Methods** Neuromodulation studies were conducted in two *in vitro* neuronal model systems (noradrenergic SH-SY5Y and T-REx-293 SERT cells). Antidepressant/anxiolytic effects were assessed via [^{3}H]MPP$^+$ uptake assays at the serotonin (SERT) and noradrenaline (NET) transporters. Non-specific uptake was measured in the presence of paroxetine and nisoxetine for SERT and NET respectively. Membrane permeability was assessed via neutral red release assays. **Results** Initial data suggests *R. rosea* main bioactive constituents and their equimolar mixture have a negligible inhibitory activity at both SERT and NET at physiological conditions. However, extracts show dose dependent, competitive inhibition. **Conclusion** MPP$^+$ uptake inhibition of extracts is not associated with membrane integrity loss as assessed via neutral red release assay. The higher efficacy of extracts suggests a possible synergistic/additive effect or a presence of an overlooked secondary metabolite.

Aims Depression is a highly prevalent and debilitating disorder that continues to increase the number of people with mental illness. Despite advances in the treatment of depression, it is estimated that 30% of patients are still resistant to antidepressant treatment. Wistar Kyoto (WKY) rats are a suitable animal model for treatment-resistant depression (TRD) in preclinical studies. Many recent scientific reports indicate that the habenula may play an important role in depression, so we focused our study on characterizing molecular differences in WKY habenular nuclei compared to Wistar Han rats (WIS). **Methods** Brain sections of WIS and WKY rats containing medial and lateral habenula (MHb and LHb) were excisted by Laser Capture Microdissection. We identified 32 miRNAs that could be potentially regulated in the habenula. The mRNA expression level was assessed using TaqMan Array Cards, which were designed based on the analysis of potential targets of significant miRNAs. **Results** Ten miRNAs significantly differentiated WKY rats from WIS rats. For mRNAs that differentiated WKY from WIS rats in the MHb (Cdkn1c, Htr7, Kcnj9, and Slc12a5), their lower expression correlated with a higher level of relevant miRNAs. In the LHb, eight mRNAs significantly differentiated WKY from WIS rats (upregulated Htr4, Drd2, Kcnj5, and Sstr4 and downregulated Htr2a, Htr7, Elk4, and Slc12a5). **Conclusion** Our results indicate the importance of the habenular nuclei as an important brain region in depression research. The basic level of molecular diversity within the habenula of WKY rats indicates its important role in TRD.

Heterogeneity of posttraumatic stress symptoms may impede timely and individualized interventions for posttraumatic stress disorder (PTSD). The present study aims to dissect the heterogeneity of posttraumatic conditions to identify novel subtypes in recently traumatized individuals and evaluate their neurobiological correlates and long-term prognosis. A data-driven approach using the agglomerative hierarchical clustering analysis was implemented to classify recently trauma-exposed individuals into specific subtypes based on clinical, behavioral, and cognitive symptom profiles which can be frequently observed in the post-traumatic period.. Two hundred forty trauma-exposed individuals and 240 age- and sex-matched healthy individuals without trauma exposure were included in the study. Subtype-specific patterns of functional connectivity in higher-order cognitive networks, longitudinal clinical outcomes, and changes in functional connectivity were also evaluated. We identified four distinct subtypes for trauma-exposed individuals according to the dimension of posttraumatic stress symptoms: the resilient, emotional symptom-predominant, behavioral symptom-predominant, and cognitive symptom-predominant subtypes. The characteristics of four identified subtypes were further validated and supported by subsequent resting-state functional neuroimaging analyses that suggested distinct functional brain organization, particularly of the higher-order cognitive networks, across subtypes. Each subtype was also distinct in long-term trajectories for posttraumatic symptoms. In the current study, we demonstrated the ability to categorize complex posttraumatic stress symptoms into the data-driven-subtypes. Our results may enhance the current understanding of mechanisms underlying the human-specific heterogeneous responses to trauma. This study may provide valuable data to develop the individualized and improved interventions, including targeting of subtype-specific characteristics.

Alzheimer's disease comprises amyloid-β and hyperphosphorylated Tau accumulation, imbalanced neuronal activity, aberrant oscillatory rhythms, and cognitive deficits. Cognitive resilience to Alzheimer's disease (CRAD) defines a novel clinical entity with amyloid-β and Tau pathologies but preserved cognition. The mechanisms underlying such neuroprotection remain undetermined, and animal models of CRAD are currently unavailable. By neuroanatomical tract-tracing, immunodetection, electrophysiological analyses, and behavioral studies, we characterize a new double transgenic mouse model accumulating amyloid-β and hyperphosphorylated Tau: J20/VLW mice. We demonstrate that J20/VLW animals exhibit preserved hippocampal oscillatory activity and cognition, as opposed to single transgenic J20 and VLW mice, which show significant alterations. Furthermore, we show that the overexpression of mutant human Tau in coexistence with amyloid-β accumulation renders a particular Tau phosphorylation signature in hippocampal interneurons. Moreover, the GABAergic septohippocampal pathway, responsible for hippocampal oscillatory activity, is preserved in J20/VLW mice, in contrast to single mutants. Our data highlight J20/VLW mice as a suitable animal model to explore the mechanisms driving cognitive preservation in CRAD. Moreover, they suggest that a differential Tau phosphorylation pattern in hippocampal interneurons prevents the loss of GABAergic septohippocampal innervation and alterations in local field potentials, thereby avoiding cognitive deficits.

Differential accumulation of Tau phosphorylated at residues Thr231, Ser262 and Thr205 in hippocampal interneurons and its modulation by Tau mutations (VLW) and amyloid-β peptide.
Alzheimer's disease (AD) is characterized by the accumulation of amyloid-β peptide (Aβ) and hyperphosphorylated Tau

protein (P-Tau). Our recent data showed a differential accumulation of Tau protein phosphorylated at residue Thr231 (pThr231) in distinct hippocampal neurons in VLW mice-a model that overexpresses mutated human Tau. Here we demonstrate that, in VLW mice, the accumulation of human P-Tau in pyramidal cells induces the phosphorylation of murine Tau at residue Thr231 in hippocampal interneurons. In addition, we show that pSer262 and pThr205 Tau are present specifically in the soma of some hippocampal interneurons in control mice. Analysis of J20 mice-a model that accumulates Aβ-and of VLW animals showed that the density of hippocampal interneurons accumulating pThr205 Tau is lower in VLW mice than in controls. In contrast, the density of interneurons accumulating pThr205 Tau in J20 mice was increased compared to controls in hippocampal regions with a higher Aβ plaque load, thereby suggesting that pThr205 Tau is induced by Aβ. No significant differences were found between the density of hippocampal interneurons positive for pSer262 Tau in VLW or J20 mice compared to control animals. We also show that pSer262 and pThr205 Tau are present in the soma of some hippocampal interneurons containing Parvalbumin, Calbindin or Calretinin in control, VLW, and J20 mice. Moreover, our results reveal that some interneurons in human hippocampi of cases of AD and control cases accumulate pSer262 and pThr205 Tau. Taken together, these data point to a specific role of pSer262 and pThr205 Tau in the soma of hippocampal interneurons in control and pathological conditions.

REGULATION OF CRTC1-MEDIATED SYNAPSE-TO-NUCLEUS COMMUNICATION BY EXCITOTOXIC ACTIVATION OF NMDA RECEPTORS

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Celia García Vilela, Anna Hagenston, Hilmar Bading
Heidelberg University, Izn Neurobiology, Heidelberg, Germany

N-methyl-D-aspartate receptors (NMDARs) are glutamate-gated calcium-permeable channels mainly localized at excitatory synapses. NMDAR function is generally linked to synaptic plasticity, learning and memory. However, sustained glutamate exposure leads to NMDA-mediated excitotoxicity, involved in neurodegenerative diseases. Distinct cellular outcomes of NMDAR stimulation depend on receptor cell surface localization. Synaptic NMDARs promote cyclic AMP-response element binding protein (CREB) activation, eventually inducing immediate early gene (IEG) expression. This coupling between excitation and gene expression is called excitation-transcription (E-T) coupling. On the other hand, extrasynaptic NMDAR activation by excessive glutamate leads to CREB shut-off and neuronal cell death. We suggest that excitotoxic NMDAR stimulation might also shut off E-T coupling by interfering with active nuclear import-dependent synapse-to-nucleus communication. Here we focus on CREB-regulated transcription coactivator 1 (CRTC1) as a representative effector molecule, because CRTC1 undergoes nuclear translocation upon synaptic activity and participates in CREB-dependent IEG expression. We aim to assess whether excitotoxic NMDAR stimulation shuts off CRTC1 nuclear translocation. We stimulated primary hippocampal cultures with two excitotoxic stimulation protocols, prolonged NMDA exposure, or brief NMDA exposure followed by a wash-out and recovery period. We then studied CRTC1 localization by immunocytochemistry. We found that NMDA pulse promoted CREB shut-off and reduced CRTC1 nuclear translocation, whereas prolonged NMDA triggered CREB shut-off while promoted CRTC1 nuclear localization. All in all, these results indicate that different excitotoxic NMDAR stimulations do not trigger the same CRTC1 nuclear translocation response, which might evoke different gene expression profiles.

THE IMPACT OF ADVANCING AGE AND INTRAOCULAR PRESSURE ELEVATION ON RETINAL GANGLION CELL SYNAPTIC CONNECTIVITY AND EXCITABILITY IN AN ACUTE MODEL OF GLAUCOMA

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Sevannah Ellis[1], Robert Hatch[1], Steven Petrou[1], Jonathan Crowston[2]
[1]The University of Melbourne, The Florey Institute Of Neuroscience And Mental Health, Parkville, Australia, [2]Duke-NUS Medical School, Singapore Eye Research Institute, Singapore, Singapore

Glaucoma is a neurodegenerative disease characterised by the dysfunction and the death of retinal ganglion cells (RGCs). The leading risk factors for developing glaucoma are elevated intraocular pressure (IOP) and increased age. Evidence suggests that the early stages of RGC dysfunction are reversible. To investigate this, we used an acute model of glaucoma that involves elevating the IOP of a mouse to produce a temporary loss of RGC function which recovers by 7-days in 3-month old mice and 28-days in 12-month old mice. The aim of our study was to investigate the changes in synaptic connectivity underlying RGC dysfunction and recovery in young and aged mice. We first quantified RGC excitatory synapses using fluorescence immunohistochemistry and microscopy. We found that excitatory synapses were reduced following IOP elevation in young and aged mice, however, these synapses did not recover. We next recorded excitatory and inhibitory postsynaptic currents (EPSCs and IPSCs) using whole-cell patch-clamp electrophysiology. EPSC amplitude was reduced following IOP elevation in young and aged mice, however, only recovered in young mice. IPSC amplitude was decreased in young mice following IOP elevation but did not recover resulting in an increased excitation/inhibition ratio. IPSC amplitude was unchanged in aged mice following IOP elevation resulting in a decreased excitation/inhibition ratio. Therefore, we can conclude that a loss of excitatory synapses underlies RGC dysfunction following IOP elevation in young and aged mice and that RGC recovery is driven by an increase in excitatory synaptic activity in young mice, but not aged mice.

Nicotinamide provides neuroprotection in glaucoma by protecting against mitochondrial and metabolic dysfunction.
Nicotinamide adenine dinucleotide (NAD) is a REDOX cofactor and metabolite essential for neuronal survival. Glaucoma is a common neurodegenerative disease in which neuronal levels of NAD decline. We assess the effects of nicotinamide (a precursor to NAD) on retinal ganglion cells (the affected neuron in glaucoma) in normal physiological conditions and across a range of glaucoma relevant insults including mitochondrial stress and axon degenerative insults. We demonstrate retinal ganglion cell somal, axonal, and dendritic neuroprotection by nicotinamide in rodent models which represent isolated ocular hypertensive, axon degenerative, and mitochondrial degenerative insults. We performed metabolomics enriched for small molecular weight metabolites for the retina, optic nerve, and superior colliculus which demonstrates that ocular hypertension induces widespread metabolic disruption, including consistent changes to α-ketoglutaric acid, creatine/creatinine, homocysteine, and glycerophosphocholine. This metabolic disruption is prevented by nicotinamide. Nicotinamide provides further neuroprotective effects by increasing oxidative phosphorylation, buffering and preventing metabolic stress, and increasing mitochondrial size and motility whilst simultaneously dampening action potential firing frequency. These data support continued determination of the utility of long-term nicotinamide treatment as a neuroprotective therapy for human glaucoma.

PTEN activation contributes to neuronal and synaptic engulfment by microglia in tauopathy.
Phosphatase and tensin homolog (PTEN) regulates synaptic density in development; however, whether PTEN also regulates synapse loss in a neurodegenerative disorder such as frontotemporal lobar degeneration with Tau deposition (FTLD-Tau) has not been explored. Here, we found that pathological Tau promotes early activation of PTEN, which precedes apoptotic caspase-3 cleavage in the rTg4510 mouse model of FTLD-Tau. We further demonstrate increased synaptic and neuronal exposure of the apoptotic signal phosphatidylserine that tags neuronal structures for microglial uptake, thereby linking PTEN

activation to synaptic and neuronal structure elimination. By applying pharmacological inhibition of PTEN's protein phosphatase activity, we observed that microglial uptake can be decreased in Tau transgenic mice. Finally, we reveal a dichotomous relationship between PTEN activation and age in FTLD-Tau patients and healthy controls. Together, our findings suggest that in tauopathy, PTEN has a role in the synaptotoxicity of pathological Tau and promotes microglial removal of affected neuronal structures.

IMPAIRED SPATIAL NAVIGATION AND AGE-DEPENDENT HIPPOCAMPAL SYNAPTIC DYSFUNCTION ACCOMPANIED BY A CHRONIC INFLAMMATORY CYTOKINE PROFILE IN DB/DB MICE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Mohammed Al-Onaizi, Ahmad Al-Sarraf, Fatema Kazem, Kawthar Braysh, Muddanna Rao, Narayana Kilarkaje
Kuwait University, Anatomy, Kuwait, Kuwait

Type 2 diabetes mellitus (T2DM) increases the risk of developing Alzheimer's Disease (AD), and an abnormal central inflammatory response has been proposed to mediate the consequences of T2DM on hippocampal synaptic integrity and cognitive function. However, the exact implications of T2DM on synaptic integrity in aging have not been investigated. Here, we investigated the effects of T2DM on AD-like pathology using the leptin receptor-deficient db/db mouse model of T2DM. We found that T2DM mice were significantly impaired spatial acquisition in the Morris Water Maze (MWM), compared to age-matched controls. Morphological analysis in young T2DM mice showed a significant neuronal loss in the dentate gyrus compared to controls, suggesting impaired dentate gyrus function. We found that GFAP immunoreactivity was significantly decreased in all regions of the hippocampus of young T2DM mice, compared to age-matched controls. We also showed that microglial activation was increased in the CA3 and dentate gyrus regions of the hippocampus in young T2DM mice, compared to controls. Interestingly, the presynaptic marker protein- synaptophysin and the postsynaptic marker protein-PSD95 did not show significant changes in the hippocampus of young T2DM mice. However, aged T2DM mice showed a robust decrease in synaptophysin and PSD95, suggesting impaired hippocampal synaptic integrity. Cytokine profiling of aged T2DM mice showed an increased expression of several pro-inflammatory cytokines in the hippocampus. Our results suggest that T2DM impairs cognitive dysfunction, leads to neuronal loss in the dentate gyrus, and reveals an age-dependent deterioration in hippocampal synaptic integrity in the diabetic state.

THE ROLE OF EARLY LIFE ADVERSITY IN A MOUSE MODEL FOR ALZHEIMER'S DISEASE PATHOLOGY

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Niek Brosens[1], Sascha Weggen[2], Paul Lucassen[3], Harm Krugers[3]
[1]University of Amsterdam, Sils, Amsterdam, Netherlands, [2]Heinrich-Heine-University, Department Of Neuropathology, Düsseldorf, Germany, [3]Brain Plasticity Group, Swammerdam Institute for Life Sciences, Faculty Of Science, University Of Amsterdam, Amsterdam, Netherlands

Stress is considered as a major environmental risk factor for Alzheimer's Disease (AD). Previous research shows that exposure to chronic early life adversity (ELA) increases the susceptibility to AD pathology in adult APPswe/PS1dE9 mice. We aimed to assess the effects of ELA that precede the accelerated onset of classical AD-pathology in this model. Wild type and APPswe/PS1dE9 mice were subjected to ELA from postnatal days 2-9 by housing the litters with limited nesting and bedding material. At 3 months old, cognitive flexibility was measured using a multiple-choice reversal learning paradigm. In addition, hippocampal synaptic activity and composition, Aβ-pathology and interneuron populations were assessed. At 3 months old, APPswe/PS1dE9 mice that were exposed to ELA were significantly impaired in reversal learning. Additionally, ELA resulted in persistent altered basal synaptic activity while Aβ-pathology was unaltered. To conclude, ELA increases the susceptibility to AD-related cognitive decline which precedes Aβ-pathology and is paralleled by altered hippocampal synaptic activity. This approach will help to understand the mechanism by which ELA accelerates AD-related pathology in the AD model and may provide insight in the development of AD pathology and the role of stress in the onset of AD.

DROSOPHILA CIRCUIT MODEL OF ALZHEIMER'S DISEASE REVEALS NEURON TYPE-SPECIFIC FUNCTIONAL CHANGES THAT ARE LINKED TO ALTERED BEHAVIOR

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Anqi Zhou[1,2,3], Tihana Jovanic[1], Jean-Baptiste Masson[3]
[1]Institut des Neuroscience Paris-Saclay, Neurosciences Cognitives & Des Réseaux, Saclay, France, [2]Université de Paris, Ed 474, Paris, France, [3]Institut Pasteur, Neuroscience And Computational Biology, Paris, France

The pathogenesis and progression of neurodegenerative diseases are poorly understood at the neural circuit level. How cellular hallmarks affect communication between neurons and translate to behavioral changes remains elusive. In order to bridge the gap between biological mechanisms and behavior during neurodegenerative processes, we built a comprehensive circuit model of Alzheimer's Disease (AD) in *Drosophila* larvae as a proof-of-concept. Previously, we mapped a three-layer mechanosensory circuit with complex mechanisms and showed that synaptic silencing of each neuron had different effects on larval behavior in response to a stimulus. Here, we modeled AD by expressing human Aß1-40 or 1-42 peptides in each neuron within the circuit. We then assayed cellular toxicity in the brain, monitored activity using Ca2+ imaging, and quantified behavior using computer vision-based software. We found that neurons within the circuit were differentially impacted by Aß expression, with some mimicking synaptic silencing. The mechanosensory chordotonal neurons were most susceptible to Aß toxicity, and its impaired activity correlated with decreased behavioral response. Interestingly, we did not observe well-formed Aß plaques at this stage, suggesting that the circuit dysfunction detected could occur prior to substantial protein aggregation. Furthermore, we showed that Ca2+ imaging data can be combined with *Drosophila* EM connectome to build a rate-based ODE model of the circuit to predict behavioral changes. Together, these results show that we can infer complex functional changes on a single-neuron level within an AD-like circuit through high-throughput whole animal behavior screens. The circuit model and methods involved can be useful in large-scale genetic and compound studies to rapidly dissect functional impacts within specific neuron types.

MULTI-ELECTRODE ARRAYS REVEAL EARLY NETWORK DYSFUNCTION IN PRIMARY HIPPOCAMPAL NEURONAL CULTURES DERIVED FROM THE APPNL-G-F MOUSE MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Richard Turner, Tanja Fuchsberger, Ole Paulsen
University of Cambridge, Department Of Physiology, Development And Neuroscience, Cambridge, United Kingdom

Amyloid β (Aβ) pathophysiology is an early and persistent feature of Alzheimer's disease (AD), developing many years before symptomatic onset. Preceding the formation of Amyloid plaques, Aβ has been shown to induce synaptic dysfunction and subsequent hyperexcitability in the hippocampus. The present study aims to elucidate how Aβ may impact hippocampal network development and function *in vitro*. Utilising 60-channel multi-electrode array (MEA) cultures of dissociated hippocampal neurons derived from both WT and App^{NL-G-F} mice — which express humanised Aβ with key familial AD mutations — we recorded the spontaneous activity of hippocampal networks over their development for the first 35 days-*in-vitro* (DIV). Both sets of hippocampal cultures displayed spontaneous and coordinated network activity by DIV7, with functional connectivity increasing progressively until the end of the culture period. However, preliminary firing and bursting analyses have suggested an accelerated maturation in App^{NL-G-F} networks, with developmental trajectories being shifted earlier than those for WT. Additionally, graph theoretical analyses have shown differences in functional network features between the two groups. Furthermore, patch-clamp experiments using the same culture model are being performed to gain mechanistic insight into cellular and synaptic deficits of the disease onset. In conclusion, cultures derived from the App^{NL-G-F} mouse model of AD reveal early deficits in hippocampal networks. These aberrations may predispose these networks to subsequent pathogenic mechanisms and understanding them may allow for targeting of earlier therapeutic intervention.

Aims: Recent studies have implicated impaired parvalbumin fast-spiking interneuron (PVIN) function in underlying deficits in gamma oscillations (rhythmic brain network activity), and cognitive decline in Alzheimer's disease (AD). We aimed to investigate amyloid beta plaque accumulation in relation to kainate- and carbachol-induced gamma oscillations and PVIN function in the *5xFAD* AD mouse model. **Methods**: Hippocampal gamma oscillations were recorded using *ex vivo* brain slices from *5xFAD* and control mice at 3-4 months (minimal plaque presence) and 12+ months (extensive plaque presence). We also performed targeted cell-attached patching of PVINs in WT and *5xFAD* brain slices during gamma oscillations to determine gamma-related PVIN function at different disease time points. Finally, brain slices were processed for immunohistochemical quantification of PVIN-related signals, PV and perineuronal nets (PNNs). **Results**: We found, as previously described, minimal hippocampal plaque presence at 3-4 months and extensive plaque burden by 12 months with significant reductions of PVINs and PNNs in 12m *5xFAD* mice. We show that detection of gamma oscillation impairment is dependent on the pharmacological approach used to initiate oscillations. Kainate-induced gamma oscillations displayed power deficits and impaired rhythmicity in *5xFAD* mice; whereas carbachol-induced oscillations exhibited only minor rhythmicity deficits in 12m *5xFAD* mice. Likewise, PVIN spiking, and gamma phase-locking were unaltered in *5xFAD* mice. **Conclusions**: Despite extensive plaque pathology and loss of PVINs, PVIN function and circuit rhythmogenesis were relatively spared in *5xFAD* mice. This highlights the complicated pathophysiology of the *5xFAD* mouse and extreme resilience of PVIN and network function in the model.

PV-specific loss of the transcriptional coactivator PGC-1α slows down the evolution of epileptic activity in an acute ictogenic model.
The transcriptional coactivator, PGC-1α (peroxisome proliferator-activated receptor γ coactivator 1α), plays a key role in coordinating energy requirement within cells. Its importance is reflected in the growing number of psychiatric and neurological conditions that have been associated with reduced PGC-1α levels. In cortical networks, PGC-1α is required for the induction of parvalbumin (PV) expression in interneurons, and PGC-1α deficiency affects synchronous GABAergic release. It is unknown, however, how this affects cortical excitability. We show here that knocking down PGC-1α specifically in the PV-expressing cells (PGC-1α) blocks the activity-dependent regulation of the synaptic proteins, SYT2 and CPLX1. More surprisingly, this cell class-specific knockout of PGC-1α appears to have a novel antiepileptic effect, as assayed in brain slices bathed in 0 Mg media. The rate of occurrence of preictal discharges developed approximately equivalently in wild-type and PGC-1α brain slices, but the intensity of these discharges was lower in PGC-1α slices, as evident from the reduced power in the γ range and reduced firing rates in both PV interneurons and pyramidal cells during these discharges. Reflecting this reduced intensity in the preictal discharges, the PGC-1α brain slices experienced many more discharges before transitioning into a seizure-like event. Consequently, there was a large increase in the latency to the first seizure-like event in brain slices lacking PGC-1α in PV interneurons. We conclude that knocking down PGC-1α limits the range of PV interneuron firing and this slows the pathophysiological escalation during ictogenesis. Parvalbumin expressing interneurons are considered to play an important role in regulating cortical activity. We were surprised, therefore, to find that knocking down the transcriptional coactivator, PGC-1α, specifically in this class of interneurons appears to slow ictogenesis. This anti-ictogenic effect is associated with reduced activity in preictal discharges, but with a far longer period of these discharges before the first seizure-like events finally start. Thus, PGC-1α knockdown may promote schizophrenia while reducing epileptic tendencies.

Paradoxical network excitation by glutamate release from VGluT3 GABAergic interneurons.
In violation of Dale's principle several neuronal subtypes utilize more than one classical neurotransmitter. Molecular identification of vesicular glutamate transporter three and cholecystokinin expressing cortical interneurons (CCKVGluT3INTs) has prompted speculation of GABA/glutamate corelease from these cells for almost two decades despite a lack of direct evidence. We unequivocally demonstrate CCKVGluT3INT-mediated GABA/glutamate cotransmission onto principal cells in adult mice using paired recording and optogenetic approaches. Although under normal conditions, GABAergic inhibition dominates CCKVGluT3INT signaling, glutamatergic signaling becomes predominant when glutamate decarboxylase (GAD) function is compromised. CCKVGluT3INTs exhibit surprising anatomical diversity comprising subsets of all known dendrite targeting CCK interneurons in addition to the expected basket cells, and their extensive circuit innervation profoundly dampens circuit excitability under normal conditions. However, in contexts where the glutamatergic phenotype of CCKVGluT3INTs is amplified, they promote paradoxical network hyperexcitability which may be relevant to disorders involving GAD dysfunction such as schizophrenia or vitamin B6 deficiency.

Feedforward inhibition ahead of ictal wavefronts is provided by both parvalbumin- and somatostatin-expressing interneurons.
There is a rapid interneuronal response to focal activity in cortex, which restrains laterally propagating activity, including spreading epileptiform activity. The interneuronal response involves intense activation of both parvalbumin- and somatostatin-expressing interneurons. Interneuronal bursting is time-locked to glutamatergic barrages in the pre-ictal period. Ca imaging using conditional expression of GCaMP6f provides an accurate readout of the evolving firing patterns in both types of interneuron. The activation profiles of the two interneuronal classes are temporally offset, with the parvalbumin population being activated first, and typically, at higher rates.

Acetylcholinesterase activity as a neurotoxicity marker within the context of experimentally-simulated hyperprolinaemia: An in vitro approach.
Hyperprolinaemia is characterized by increased tissue accumulation of proline (Pro) and is known to exert serious cognitive and/or neuropsychiatric symptomatology as a direct result of Pro accumulation in the brain. The aim of this study was to explore a putative link between experimentally-simulated hyperprolinaemia and the activity of acetylcholinesterase (AChE); a crucial neurotoxicity marker. In vitro experiments were undertaken on purified eel-derived AChE, as well as on adult mouse brain homogenates, in order to examine the effect of a spectrum of Pro concentrations (3, 30, 500, and 1000 μM) on this marker. Our data showed that although Pro exerted a significant inhibitory effect on pure AChE activity, mouse brain-derived membrane-bound AChE activity was found either unaltered or significantly increased following incubation with Pro. The use of AChE activity as a neurotoxicity marker within the context of experimentally-simulated hyperprolinaemia should be considered with caution and in parallel with a number of other experimental parameters.

DIETARY IMPACTS ON NEURONAL FUNCTION AND LEARNING CAPACITY IN A DROSOPHILA MODEL OF NEURODEGENERATION.

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Vladyslava Yarosh, Joern Steinert, William Neil, Ellie Herniman, Sanjana Mamidipalli, Aelfwin Stone, Mihir Kocherlacota
University of Nottingham, Physiology, Pharmacology And Neuroscience, Nottingham, United Kingdom

The gut-brain axis (GBA) is defined as a bidirectional channel of communication between the brain and the enteric nervous system linked by neurons of the sympathetic and parasympathetic systems and circulating hormones. The gut microbiota may have a large influence on neurological function with the microbiota playing a major role in the Aβ pathology. We hypothesise that a high-fat diet (HFD) will compromise neuronal function mediated by changes in the gut microbiota of *Drosophila*. We aim at characterising neuronal activity and learning & memory function following changes in the diet. *Drosophila* larvae were raised under standard conditions or supplemented with 10% coconut oil. Glutamatergic synaptic responses were measured at the *Drosophila* larval neuromuscular junction. Motoneurons were stimulated and evoked or spontaneous excitatory postsynaptic currents (e/sEJCs) were recorded in a two-electrode voltage-clamp. Larvae underwent olfactory conditioning with odour-reward training and testing were adapted from Michels et al. (2017). Statistical analyses were performed using Mann-Whitney-U and t-tests. We show that HFD induces a marked reduction in neurotransmission with reduced eEJC amplitudes (Ctrl: -88±6nA; HFD: -60±5nA, $p=0.011$) and frequencies of sEJCs. We found that the HFD diet impairs olfactory learning in larvae with preferences indices (PI) being significantly reduced in the test group (PI Ctrl: 0.225, HFD: 0.100, $p<0.001$). We conclude that the impact of the HFD on neuronal function, as assessed on the level of larval NMJ physiology and learning & memory may act via the GBA. A compromised gut microbiome may thus facilitate neurodegeneration in the peripheral and central nervous systems.

NICOTINIC RECEPTOR MODULATION OF EARLY ALZHEIMER'S DISEASE IN (MOUSE) HIPPOCAMPUS

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Marie Sabec, Uwe Maskos
Institut Pasteur, Integrative Neurobiology Of Cholinergic Systems, Paris, France

Treatments for Alzheimer's disease (AD) commonly rely on elevating cholinergic function in the brain, however such interventions are symptomatic and do not prevent the disease's progression. β-amyloid, a peptide thought to underlie neural disruption reported in early AD development, can interact with the cholinergic system though nicotinic acetylcholine receptors (nAChRs). Previous studies from our group revealed that a genetic loss of β2 nAChR subunits could protect against memory impairment which is induced by β-amyloid over-expression. The presented work investigates the influence of nAChR on β-amyloid induced synaptic and network dysfunction in the hippocampus, and how such modulation may affect the manifestation of cognitive deficits in early AD pathogenesis. We developed a model of localized β-amyloid over-expression by viral transduction of mouse dentate gyrus (DG). This local model is used to test the impact of genetic and pharmacological inactivation of nAChRs on memory function and neural activity through behavioural analysis, *in vivo* two-photon calcium imaging, and immunofluorescent techniques. An early-onset development of cognitive deficits and DG hyperactivity was observed in the model. Furthermore, whilst pharmacological β2 nAChR inhibition was able to protect against β-amyloid induced impairments, this was not associated with a normalization of the DG network activity. Thus, β2 nAChR inactivity is able to protect against β-amyloid induced cognitive dysfunction in a manner independent to changes in overall activity levels within the DG. Identification of the specific nicotinic-β-amyloid interactions underlying the reported protection will facilitate more targeted cholinergic therapies against early AD and provide mechanistic insights essential for the development of preventative medicine.

EXCITATORY/INHIBITORY IMBALANCE IN A TRANSGENIC MOUSE MODEL OF ALZHEIMER DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Floriane Payet, Sylvie Boisseau, Alain Buisson, Fabien Lanté
Univ. Grenoble Alpes, Inserm U1216, Grenoble, France

Alzheimer's disease (AD) is a neurodegenerative disease characterized by a long asymptomatic phase during which disturbances in neurotransmission has been described.To explore the pathogenic outcome occurring during the prodromal period, our team use one-month-old APP/PS1-21 mice. This mouse model simulated a key aspect of AD prodromal phase with an overproduction of soluble Aβ oligomers (Aβo), starting at P14 without amyloid plaque formation and cognitive alteration.Using a multimodal approach combining extracellular electrophysiology, patch-clamp recordings on acute hippocampal slices and biochemistry techniques, our study aims at further understanding how Aβo alter synaptic transmission in one-month-old APP/PS1 mice during the prodromal phase. With extracellular field recordings in CA1 hippocampal region, we showed an increase of the basal glutamatergic synaptic transmission.We further showed, using patch clamp recordings on CA1 neurons, that this hyperactivity is associated with a disruption of the inhibitory synaptic transmission. Indeed, a 30% decrease in the frequency and 50% decrease in the amplitude of inhibitory spontaneous currents was observed in APP/PS1-21 acute slices.We then showed that bath application of Aβo (100 nm) induced similar reductions of the inhibitory spontaneous currents in CA1 neurons of acute hippocampal slice of WT mice demonstrating that previous alterations were Aβo dependent.During the prodromal phase of AD, we have shown that Aβo overproduction induced CA1 neurons hyperactivity by reducing the inhibitory synaptic transmission in APP/PS1-21 mice.These early modifications could be at the origin of the long-term alterations observed in AD and could therefore constitute a new therapeutic target.

PHYSIOLOGICAL ROLE OF THE FULL-LENGTH AMYLOID PRECURSOR PROTEIN (APP) IN PRESYNAPTIC PLASTICITY AND INFORMATION TRANSFER WITHIN HIPPOCAMPAL CA3 CIRCUITS

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Ana Moreira-De-Sá, Gaël Barthet, Tomas Jordà-Siquer, Noelle Grosjean, Christophe Mulle

The full-length amyloid precursor protein (APP), a key player in Alzheimer's disease (AD), is ubiquitously expressed throughout the brain. It is known to be abundantly expressed in presynaptic compartments where it interacts with proteins of the presynaptic release machinery. However, the physiological functions of APP in the central nervous system still remain elusive. Here we study the physiological role of APP in presynaptic plasticity and information transfer within the hippocampus. This will help understanding whether the disruption of its functions can contribute to the pathophysiology of AD. We deleted APP and the related protein APLP2 in selected neuronal populations using a viral gene transfer strategy in APP/APLP2 double floxed mice. By combining optogenetics and *ex vivo* electrophysiology, we found that the selective deletion of APP in dentate gyrus granule cells impairs presynaptic short-term plasticity at mossy-fiber to CA3 pyramidal cells synapses, without altering the intrinsic spiking properties of granule cells. Furthermore, selective deletion of APP/APLP2 in GABAergic interneurons within CA3 influences the properties of inhibitory synaptic currents in CA3 pyramidal cells. Altogether, our data supports a role of presynaptic APP in synaptic transmission and plasticity mechanisms at identified excitatory and inhibitory synapses, and thus sheds light on the physiological contribution of full-length APP to hippocampal circuit activity.

ACCUMULATION AND NEURON-TO-GLIA SPREAD OF HUMAN TAU PROTEINS IN AGEING MICE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Aggregation and propagation of misfolded pathological Tau proteins (pTau) correlate with the severity of neurological symptoms of tauopathies, including memory impairment. We investigated the spread of pTau in 2-27-month-old THY-Tau22 transgenic mice and sought to understand its impact on *in vivo* neuronal activity and memory. The distribution of pTau correlated with age and neurodegeneration and was prominent in the hippocampus, subiculum and basolateral amygdala. We discovered that oligodendrocytes accumulated pTau in older mice, which we confirmed with electron microscopy, suggesting pTau may spread from neurons to glia. To understand the effects of pTau on hippocampus-dependent memory, we tested mice in three tasks. While the spontaneous spatial novelty preference task revealed reduced short-term familiarity, the water-escape Y-maze task revealed unimpaired spatial reference memory. In a non-matching-to-place T-maze task, spatial working memory performance was similar in transgenic and non-transgenic littermates. To investigate neuronal and network activity, we performed single-neuron glass-electrode recordings and juxtacellular labelling in awake mice, observing similar activity for both genotypes. We also recorded multiple single-unit activities during 'goal-directed' virtual navigation, showing a loss of higher-firing complex spiking (pyramidal) cells in aged transgenic mice. We conclude that pTau accumulation in THY-Tau22 mice leads to localized disruption of predominantly higher-firing complex spiking cells without affecting network activity, along with specific deficits in the familiarity of spatial cues. The spread of pTau to oligodendrocytes via myelinated axons suggests a potential mechanism for their propagation in human tauopathies such as progressive supranuclear palsy and corticobasal degeneration.

N-methyl-D-aspartate receptors (NMDARs) are pivotal players in the synaptic transmission and synaptic plasticity underlying learning and memory. Accordingly, dysfunction of NMDARs has been implicated in the pathophysiology of Alzheimer's disease (AD). Aims: to investigate the expression and subcellular localization of GluN1, the obligatory subunit of NMDARs, in the hippocampus of P301S mice. Methods: We used histoblot and SDS-digested freeze-fracture replica labelling (SDS-FRL) techniques. Results: Histoblots showed that GluN1 expression was significantly reduced in the hippocampus of P301S mice in a laminar-specific manner at 10 months of age but was unaltered at 3 months. By SDS-FRL, excitatory synapses and extrasynaptic sites on pyramidal cells and interneuron were analysed throughout the CA1 field. Density of GluN1 was high at synaptic sites and substantially lower at extrasynaptic sites. Labelling density for GluN1 in excitatory synapses on spines was significantly reduced in P301S mice, compared to age-matched wild type mice, in the three strata. Density for synaptic GluN1 on interneuron dendrites was significantly reduced in P301S mice in the strata oriens and radiatum, but unaltered in the stratum lacunosum-moleculare. Labelling density for GluN1 at extrasynaptic sites showed no significant differences in pyramidal cells, and only increased density in the interneuron dendrites of the stratum radiatum. Conclusions: This differential alteration of synaptic versus extrasynaptic NMDARs supports the notion that the progressive accumulation of phospho-tau is associated with changes in NMDARs, in the absence of Aβ pathology. Cellular and Subcellular Localisation of Kv4-Associated KChIP Proteins in the Rat Cerebellum.
The K channel interacting proteins (KChIPs) are a family of cytosolic proteins that interact with Kv4 channels, leading to higher current density, modulation of channel inactivation and faster recovery from inactivation. Using immunohistochemical techniques at the light and electron microscopic level combined with quantitative analysis, we investigated the cellular and subcellular localisation of KChIP3 and KChIP4 to compare their distribution patterns with those for Kv4.2 and Kv4.3 in the cerebellar cortex. Immunohistochemistry at the light microscopic level demonstrated that KChIP3, KChIP4, Kv4.2 and Kv4.3 proteins were widely expressed in the cerebellum, with mostly overlapping patterns. Immunoelectron microscopic techniques showed that KChIP3, KChIP4, Kv4.2 and Kv4.3 shared virtually the same somato-dendritic domains of Purkinje cells and granule cells. Application of quantitative approaches showed that KChIP3 and KChIP4 were mainly membrane-associated, but also present at cytoplasmic sites close to the plasma membrane, in dendritic spines and shafts of Purkinje cells (PCs) and dendrites of granule cells (GCs). Similarly, immunoparticles for Kv4.2 and Kv4.3 were observed along the plasma membrane and at intracellular sites in the same neuron populations. In addition to the preferential postsynaptic distribution, KChIPs and Kv4 were also distributed presynaptically in parallel fibres and mossy fibres. Immunoparticles for KChIP3, KChIP4 and Kv4.3 were detected in parallel fibres, and KChIP3, KChIP4, Kv4.2 and Kv4.3 were found in parallel fibres, indicating that composition of KChIP and Kv4 seems to be input-dependent. Together, our findings unravelled previously uncharacterised KChIP and Kv4 subcellular localisation patterns in neurons, revealed that KChIP have additional Kv4-unrelated functions in the cerebellum and support the formation of macromolecular complexes between KChIP3 and KChIP4 with heterotetrameric Kv4.2/Kv4.3 channels.

The Expression and Localisation of G-Protein-Coupled Inwardly Rectifying Potassium (GIRK) Channels Is Differentially

Altered in the Hippocampus of Two Mouse Models of Alzheimer's Disease.
G protein-gated inwardly rectifying K (GIRK) channels are the main targets controlling excitability and synaptic plasticity on hippocampal neurons. Consequently, dysfunction of GIRK-mediated signalling has been implicated in the pathophysiology of Alzheimer´s disease (AD). Here, we provide a quantitative description on the expression and localisation patterns of GIRK2 in two transgenic mice models of AD (P301S and APP/PS1 mice), combining histoblots and immunoelectron microscopic approaches. The histoblot technique revealed differences in the expression of GIRK2 in the two transgenic mice models. The expression of GIRK2 was significantly reduced in the hippocampus of P301S mice in a laminar-specific manner at 10 months of age but was unaltered in APP/PS1 mice at 12 months compared to age-matched wild type mice. Ultrastructural approaches using the pre-embedding immunogold technique, demonstrated that the subcellular localisation of GIRK2 was significantly reduced along the neuronal surface of CA1 pyramidal cells, but increased in its frequency at cytoplasmic sites, in both P301S and APP/PS1 mice. We also found a decrease in plasma membrane GIRK2 channels in axon terminals contacting dendritic spines of CA1 pyramidal cells in P301S and APP/PS1 mice. These data demonstrate for the first time a redistribution of GIRK channels from the plasma membrane to intracellular sites in different compartments of CA1 pyramidal cells. Altogether, the pre- and post-synaptic reduction of GIRK2 channels suggest that GIRK-mediated alteration of the excitability in pyramidal cells could contribute to the cognitive dysfunctions as described in the two AD animal models.

Expression, Cellular and Subcellular Localisation of Kv4.2 and Kv4.3 Channels in the Rodent Hippocampus.
The Kv4 family of voltage-gated K^+ channels underlie the fast transient (A-type) outward K^+ current. Although A-type currents are critical to determine somato-dendritic integration in central neurons, relatively little is known about the precise subcellular localisation of the underlying channels in hippocampal circuits. Using histoblot and immunoelectron microscopic techniques, we investigated the expression, regional distribution and subcellular localisation of Kv4.2 and Kv4.3 in the adult brain, as well as the ontogeny of their expression during postnatal development. Histoblot demonstrated that Kv4.2 and Kv4.3 proteins were widely expressed in the brain, with mostly non-overlapping patterns. During development, levels of Kv4.2 and Kv4.3 increased with age but showed marked region- and developmental stage-specific differences. Immunoelectron microscopy showed that labelling for Kv4.2 and Kv4.3 was differentially present in somato-dendritic domains of hippocampal principal cells and interneurons, including the synaptic specialisation. Quantitative analyses indicated that most immunoparticles for Kv4.2 and Kv4.3 were associated with the plasma membrane in dendritic spines and shafts, and that the two channels showed very similar distribution patterns in spines of principal cells and along the surface of granule cells. Our data shed new light on the subcellular localisation of Kv4 channels and provide evidence for their non-uniform distribution over the plasma membrane of hippocampal neurons.

Alzheimer´s disease (AD) is associated with impaired cognitive functions. We recently established a link between impaired function of the inhibitory neurons expressing the parvalbumin protein (PV), and cognitive impairments in AD. PV cells are associated with perineuronal net (PNN), an extracellular matrix appearing at the end of neuronal maturation, the presence of which is reduced in the hippocampus of the Tg2576 mouse (AD), perhaps contributing to memory deficits. Importantly, exposure to enriched environment (EE), which has proven long-lasting beneficial effects on memory in AD subjects, also rescues PV/PNN deficits. Here, we hypothesize that EE-induced cognitive improvements in Tg2576 mice are supported by a remodeling of hippocampal PV/PNN cell network. In this study, we injected chondroitinase-ABC (ChABC), a PNN-degrading enzyme, into the area CA1 of 5-month-old Tg2576 and non-transgenic mice, the day before placing them into EE for 10 days. Doing so, we were aiming at preventing EE-induced PNN formation in the area CA1, specifically. Then, 20 days later, the mice were subjected to the object location test (CA1), and social memory (CA2). This allowed us evaluating the link between absence of PNN and memory performance in a specific task. Our data show that a 10-day stay in EE was sufficient to induce memory improvements of Tg2576 mice. We observed that blocking EE-induced PNN in area CA1 of AD mice prevented improvement of memory dependant of CA1 area. This demonstrates that increased PNN around PV cells is necessary to the long-lasting beneficial effects of EE on cognitive functions of AD mice.

IMPLICATION OF SFRP1 IN ALTERED SYNAPTIC PLASTICITY ASSOCIATED WITH ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Guadalupe Pereyra Gómez[1], María Inés Mateo Ruiz[2], María Martín Bermejo[2], José Delgado García[3], Pilar Esteve Pastor[2], Paola Bovolenta[4]
[1]Centro de Biología Molecular Severo Ochoa, Unidad De Homeostasis De Tejidos Y Órganos, Madrid, Spain, [2]Centro de Biología Molecular Severo Ochoa, Unidad De Homeostasis De Tejidos Y órganos, Madrid, Spain, [3]Universidad Pablo de Olavide, División De Neurociencias, Sevills, Spain, [4]Centro de Biologia Molecular Severo Ochoa, CSIC-UAM, Tissue And Organ Homeostasis Program, Madrid, Spain

SFRP1 is an extracellular protein that is normally expressed at low concentrations in the adult brain. We have previously shown that the amount of SFRP1 protein increases in the brains of Alzheimer's Disease patients and of the related APP;PS1 mouse model, contributing to AD pathogenesis by favouring the accumulation of toxic ab peptides. Neutralization of Sfrp1 activity in APP;PS1 mice not only decreases the formation of ab peptides, but also counteracts brain inflammation and maintains synaptic plasticity (Esteve *et al.,* 2019), suggesting that SFRP1 might have pleiotropic effect in the brain. According to this hypothesis, we have found that astrocyte-derived SFRP1 fosters microglia activation in different models of neuroinflammation (Rueda-Carrasco *et al*., 2021). Whether SFRP1 directly influences synaptic plasticity, or its effect is secondary to the existing neuropathological feed-forward mechanism remains however undetermined. To address this question, we generated a transgenic mouse model overexpressing *Sfrp1* in astrocytes (GFAP-tTA;TRE-Sfrp1). We will show that adult GFAP-tTA;TRE-Sfrp1 mice present an allele-dependent increase in Sfrp1 expression, which is associated with a decrease in dendritic and spine density already at two months of age, as determined by confocal and EM analysis. These defects are followed by the appearance of cognitive decline and long-term potentiation (LTP) impairment. Our data indicates that Sfrp1 has a direct impact on synaptic plasticity that, together with its reported effect on APP processing or microglial activation, support the contention that SFRP1 might have a pleiotropic effect in neurodegenerative diseases.

SFRP1 modulates astrocyte-to-microglia crosstalk in acute and chronic neuroinflammation.
Neuroinflammation is a common feature of many neurodegenerative diseases. It fosters a dysfunctional neuron-microglia-astrocyte crosstalk that, in turn, maintains microglial cells in a perniciously reactive state that often enhances neuronal damage. The molecular components that mediate this critical communication are not fully explored. Here, we show that secreted frizzled-related protein 1 (SFRP1), a multifunctional regulator of cell-to-cell communication, is part of the cellular crosstalk underlying neuroinflammation. In mouse models of acute and chronic neuroinflammation, SFRP1, largely astrocyte-derived, promotes and sustains microglial activation, and thus a chronic inflammatory state. SFRP1 promotes the upregulation of components of the hypoxia-induced factor-dependent inflammatory pathway and, to a lower extent, of those downstream of the nuclear factor-kappa B. We thus propose that SFRP1 acts as an astrocyte-to-microglia amplifier of neuroinflammation, representing a potential valuable therapeutic target for counteracting the harmful effect of chronic inflammation in several neurodegenerative diseases.

Sfrp1 deficiency makes retinal photoreceptors prone to degeneration.
Millions of individuals worldwide suffer from impaired vision, a condition with multiple origins that often impinge upon the light sensing cells of the retina, the photoreceptors, affecting their integrity. The molecular components contributing to this integrity are however not yet fully understood. Here we have asked whether Secreted Frizzled Related Protein 1 (SFRP1) may be one of such factors. SFRP1 has a context-dependent function as modulator of Wnt signalling or of the proteolytic activity of A Disintegrin And Metalloproteases (ADAM) 10, a main regulator of neural cell-cell communication. We report that in Sfrp1 mice, the outer limiting membrane (OLM) is discontinuous and the photoreceptors disorganized and more prone to light-

induced damage. Sfrp1 loss significantly enhances the effect of the Rpe65 genetic variant -present in the mouse genetic background- which confers sensitivity to light-induced stress. These alterations worsen with age, affect visual function and are associated to an increased proteolysis of Protocadherin 21 (PCDH21), localized at the photoreceptor outer segment, and N-cadherin, an OLM component. We thus propose that SFRP1 contributes to photoreceptor fitness with a mechanism that involves the maintenance of OLM integrity. These conclusions are discussed in view of the broader implication of SFRP1 in neurodegeneration and aging.

Elevated levels of Secreted-Frizzled-Related-Protein 1 contribute to Alzheimer's disease pathogenesis.
The deposition of aggregated amyloid-β peptides derived from the pro-amyloidogenic processing of the amyloid precurson protein (APP) into characteristic amyloid plaques (APs) is distinctive to Alzheimer's disease (AD). Alternative APP processing via the metalloprotease ADAM10 prevents amyloid-β formation. We tested whether downregulation of ADAM10 activity by its secreted endogenous inhibitor secreted-frizzled-related protein 1 (SFRP1) is a common trait of sporadic AD. We demonstrate that SFRP1 is significantly increased in the brain and cerebrospinal fluid of patients with AD, accumulates in APs and binds to amyloid-β, hindering amyloid-β protofibril formation. Sfrp1 overexpression in an AD-like mouse model anticipates the appearance of APs and dystrophic neurites, whereas its genetic inactivation or the infusion of α-SFRP1-neutralizing antibodies favors non-amyloidogenic APP processing. Decreased Sfrp1 function lowers AP accumulation, improves AD-related histopathological traits and prevents long-term potentiation loss and cognitive deficits. Our study unveils SFRP1 as a crucial player in AD pathogenesis and a promising AD therapeutic target.

NPC1 enables cholesterol mobilization during long-term potentiation that can be restored in Niemann-Pick disease type C by CYP46A1 activation.
NPC is a neurodegenerative disorder characterized by cholesterol accumulation in endolysosomal compartments. It is caused by mutations in the gene encoding NPC1, an endolysosomal protein mediating intracellular cholesterol trafficking. Cognitive and psychiatric alterations are hallmarks in NPC patients pointing to synaptic defects. However, the role of NPC1 in synapses has not been explored. We show that NPC1 is present in the postsynaptic compartment and is locally translated during LTP. A mutation in a region of the NPC1 gene commonly altered in NPC patients reduces NPC1 levels at synapses due to enhanced NPC1 protein degradation. This leads to shorter postsynaptic densities, increased synaptic cholesterol and impaired LTP in NPC1 mice with cognitive deficits. NPC1 mediates cholesterol mobilization and enables surface delivery of CYP46A1 and GluA1 receptors necessary for LTP, which is defective in NPC1 mice. Pharmacological activation of CYP46A1 normalizes synaptic levels of cholesterol, LTP and cognitive abilities, and extends life span of NPC1 mice. Our results unveil NPC1 as a regulator of cholesterol dynamics in synapses contributing to synaptic plasticity, and provide a potential therapeutic strategy for NPC patients.

TRACKING THE SYNAPTIC ALTERATIONS IN A KNOCK-IN MOUSE MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Luis Arroyo García[1], Giusy Pizzirusso[1,2], Julen Goikolea[1], Maria Latorre Leal[1], Silvia Maioli[1], Per Nilsson[1], Klas Blomgren[2], André Fisahn[1]

Aims: Our main goal is to investigate the synaptic alterations that lead to brain oscillatory activity impairment in Alzheimer's disease (AD). To do so, we use a knock-in mouse model of AD (*App^{NL-G-F}*) and evaluate gamma oscillations in vitro. Using this model, we have demonstrated that the hippocampal oscillatory activity in the gamma band is strongly impaired before the onset of amyloid-beta (Aβ) plaques. However, the exact breaking point during the amyloidogenic progression in the *App^{NL-G-F}* model is still unknown. Here, we aim to track the breaking point of the hippocampal gamma oscillations impairment in the *App^{NL-G-F}* model. Moreover, we aim to compare hippocampal oscillatory activity in *App^{NL-G-F}* males and females. Methods: We use *in vitro* electrophysiological techniques to analyse the circuitry involving gamma oscillations, inhibitory interneurons, and excitatory pyramidal cells in the hippocampal network. We use *App^{NL-G-F}* males and females to evaluate the oscillatory activity every five days from 1 to 2 months of age. Results: *In vitro*-gamma oscillations degrade progressively and become significantly impaired at postnatal day (PD) 50. Spike-gamma coupling from inhibitory interneurons is impaired after PD 50. Moreover, our results are not sex-dependent since we found the same significant impairment in males and females of the *App^{NL-G-F}* model. Conclusions: Our results demonstrate that the amyloidogenic progression in the *App^{NL-G-F}* model causes a synaptic collapse that affects the cognitive-relevant hippocampal gamma oscillations before the onset of Aβ plaques. These results provide a time window to explore the pathological synaptic modifications in the hippocampal network.

Functionally-distinct pyramidal cell subpopulations during gamma oscillations in mouse hippocampal area CA3.
Gamma oscillations (γ-oscillations) in hippocampal area CA3 are essential for memory function. Particularly, CA3 is involved in the memory related process pattern completion, which is linked with the γ-oscillations in human hippocampus. Recent studies suggest that heterogeneity in the functional properties of pyramidal cells (PCs) in CA3 plays an important role in hippocampal function. By performing concomitant recordings of PC activity and network γ-oscillations in CA3 we found three functionally-different PC subpopulations. PCs with high spike-frequency adaptation (hA) have the strongest action potential gamma phase-coupling, PCs with low adaptation (lA) show lower phase-coupling and PCs displaying a burst-firing pattern (B) remained quiescent. In addition, we discovered that hA display the highest excitatory/inhibitory drive, followed by lA, and lastly B. In conclusion, our data advance the hypothesis that PCs in CA3 are organized into subpopulations with distinct functional roles for cognition-relevant network dynamics and provide new insights in the physiology of hippocampus.

Impaired spike-gamma coupling of area CA3 fast-spiking interneurons as the earliest functional impairment in the App mouse model of Alzheimer's disease.
In Alzheimer's disease (AD) the accumulation of amyloid-β (Aβ) correlates with degradation of cognition-relevant gamma oscillations. The gamma rhythm relies on proper neuronal spike-gamma coupling, specifically of fast-spiking interneurons (FSN). Here we tested the hypothesis that decrease in gamma power and FSN synchrony precede amyloid plaque deposition and cognitive impairment in App knock-in mice (App). The aim of the study was to evaluate the amyloidogenic pathology progression in the novel App mouse model using in vitro electrophysiological network analysis. Using patch clamp of FSNs and pyramidal cells (PCs) with simultaneous gamma oscillation recordings, we compared the activity of the hippocampal network of wild-type mice (WT) and the App mice at four disease stages (1, 2, 4, and 6 months of age). We found a severe degradation of gamma oscillation power that is independent of, and precedes Aβ plaque formation, and the cognitive impairment reported previously in this animal model. The degradation correlates with increased Aβ concentration in the brain. Analysis on the cellular level showed an impaired spike-gamma coupling of FSN from 2 months of age that correlates with the

degradation of gamma oscillations. From 6 months of age PC firing becomes desynchronized also, correlating with reports in the literature of robust Aβ plaque pathology and cognitive impairment in the App mice. This study provides evidence that impaired FSN spike-gamma coupling is one of the earliest functional impairment caused by the amyloidogenic pathology progression likely is the main cause for the degradation of gamma oscillations and consequent cognitive impairment. Our data suggests that therapeutic approaches should be aimed at restoring normal FSN spike-gamma coupling and not just removal of Aβ.

Astrocyte-mediated switch in spike timing-dependent plasticity during hippocampal development.
Presynaptic spike timing-dependent long-term depression (t-LTD) at hippocampal CA3-CA1 synapses is evident until the 3 postnatal week in mice, disappearing during the 4 week. At more mature stages, we found that the protocol that induced t-LTD induced t-LTP. We characterized this form of t-LTP and the mechanisms involved in its induction, as well as that driving this switch from t-LTD to t-LTP. We found that this t-LTP is expressed presynaptically at CA3-CA1 synapses, as witnessed by coefficient of variation, number of failures, paired-pulse ratio and miniature responses analysis. Additionally, this form of presynaptic t-LTP does not require NMDARs but the activation of mGluRs and the entry of Ca into the postsynaptic neuron through L-type voltage-dependent Ca channels and the release of Ca from intracellular stores. Nitric oxide is also required as a messenger from the postsynaptic neuron. Crucially, the release of adenosine and glutamate by astrocytes is required for t-LTP induction and for the switch from t-LTD to t-LTP. Thus, we have discovered a developmental switch of synaptic transmission from t-LTD to t-LTP at hippocampal CA3-CA1 synapses in which astrocytes play a central role and revealed a form of presynaptic LTP and the rules for its induction.

Modulation of Kv3.1/Kv3.2 promotes gamma oscillations by rescuing Aβ-induced desynchronization of fast-spiking interneuron firing in an AD mouse model in vitro.
Gamma oscillations (30-80 Hz) are important for cognitive functions and depend on the synchronized activity of fast-spiking interneurons (FSN), which is crucial for network stability. Gamma oscillations are degraded in Alzheimer's disease (AD) patients exhibiting cognitive impairment, with the degree of cognitive decline correlating with the severity of gamma disruption in response to neurotoxic amyloid-beta peptide (Aβ). Small molecule compounds EX15 and RE01 modulate Kv3.1/Kv3.2 potassium channels on FSN, resulting in faster activation kinetics and increased firing frequency, suggesting direct consequences for cognition-relevant gamma oscillations, particularly in a situation where network activity is pathologically compromised in the presence of neurotoxic Aβ. Using electrophysiological techniques in an in vitro AD model, we found a significant effect of EX15 and RE01 with respect to counteracting toxic Aβ effects on neuronal dynamics, advocating for targeting FSN activity to rescue cognitive performance from impairment caused by neurodegenerative triggers.

Amphetamine sensitization alters hippocampal neuronal morphology and memory and learning behaviors.
It is known that continuous abuse of amphetamine (AMPH) results in alterations in neuronal structure and cognitive behaviors related to the reward system. However, the impact of AMPH abuse on the hippocampus remains unknown. The aim of this study was to determine the damage caused by AMPH in the hippocampus in an addiction model. We reproduced the AMPH sensitization model proposed by Robinson et al. in 1997 and performed the novel object recognition test (NORt) to evaluate learning and memory behaviors. After the NORt, we performed Golgi-Cox staining, a stereological cell count, immunohistochemistry to determine the presence of GFAP, CASP3, and MT-III, and evaluated oxidative stress in the hippocampus. We found that AMPH treatment generates impairment in short- and long-term memories and a decrease in neuronal density in the CA1 region of the hippocampus. The morphological test showed an increase in the total dendritic length, but a decrease in the number of mature spines in the CA1 region. GFAP labeling increased in the CA1 region and MT-III increased in the CA1 and CA3 regions. Finally, we found a decrease in Zn concentration in the hippocampus after AMPH treatment. An increase in the dopaminergic tone caused by AMPH sensitization generates oxidative stress, neuronal death, and morphological changes in the hippocampus that affect cognitive behaviors like short- and long-term memories.

Apomorphine effects on the hippocampus.
Apomorphine is a non-specific dopamine receptor agonist that has been used in the treatment of some diseases and mental disorders. Its use has particularly well documented in Parkinson's disease (PD). The dopaminergic agonists like apomorphine

are related to oxidative processes that could induce cell damage and the functional impairment of some structures in the brain. However, most information about apomorphine in literature is focused on the improvement of the motor problems characteristic of PD, but little is known about the effects on cognitive behaviors and brain structures indirectly related to motor function. The presence of dopaminergic receptors in the hippocampus has recently been discovered, in connection with cognitive behaviors like learning and memory, these receptors are needed in neuronal plasticity. There has been a growing interest to know if this structure could be compromised by the effect of apomorphine and elucidate if part of the cognitive impairment present in the PD is due to the effect of apomorphine. In this mini-review, we summarized how apomorphine has been used since its creation, we discuss the latest information about its effect on the hippocampus and also the future perspectives to fully understand the effects of this compound.

Adenosine Receptor-Mediated Developmental Loss of Spike Timing-Dependent Depression in the Hippocampus.
Critical periods of synaptic plasticity facilitate the reordering and refining of neural connections during development, allowing the definitive synaptic circuits responsible for correct adult physiology to be established. Presynaptic spike timing-dependent long-term depression (t-LTD) exists in the hippocampus, which depends on the activation of NMDARs and that probably fulfills a role in synaptic refinement. This t-LTD is present until the third postnatal week in mice, disappearing in the fourth week of postnatal development. We were interested in the mechanisms underlying this maturation related loss of t-LTD and we found that at CA3-CA1 synapses, presynaptic NMDA receptors (pre-NMDARs) are tonically active between P13 and P21, mediating an increase in glutamate release during this critical period of plasticity. Conversely, at the end of this critical period (P22-P30) and coinciding with the loss of t-LTD, these pre-NMDARs are no longer tonically active. Using immunogold electron microscopy, we demonstrated the existence of pre-NMDARs at Schaffer collateral synaptic boutons, where a decrease in the number of pre-NMDARs during development coincides with the loss of both tonic pre-NMDAR activation and t-LTD. Interestingly, this t-LTD can be completely recovered by antagonizing adenosine type 1 receptors (A1R), which also recovers the tonic activation of pre-NMDARs at P22-P30. By contrast, the induction of t-LTD was prevented at P13-P21 by an agonist of A1R, as was tonic pre-NMDAR activation. Furthermore, we found that the adenosine that mediated the loss of t-LTD during the fourth week of development is supplied by astrocytes. These results provide direct evidence for the mechanism that closes the window of plasticity associated with t-LTD, revealing novel events probably involved in synaptic remodeling during development.

The Effects of Non-selective Dopamine Receptor Activation by Apomorphine in the Mouse Hippocampus.
Apomorphine is a dopamine receptor agonist that activates D-D dopamine receptors and that is used to treat Parkinson's disease (PD). However, the effect of apomorphine on non-motor activity has been poorly studied, and likewise, the effects of dopaminergic activation in brain areas that do not fulfill motor functions are unclear. The aim of this study was to determine how dopamine receptor activation affects behavior, as well as plasticity, morphology, and oxidative stress in the hippocampus. Adult mice were chronically administered apomorphine (1 mg/kg for 15 days), and the effects on memory and learning, synaptic plasticity, dendritic length, inflammatory responses, and oxidative stress were evaluated. Apomorphine impaired learning and long-term memory in mice, as evaluated in the Morris water maze test. In addition, electrophysiological recording of field excitatory postsynaptic potentials (fEPSP) indicated that the long-term potentiation (LTP) of synaptic transmission in the CA1 region of the hippocampus was fully impaired by apomorphine. In addition, a Sholl analysis of Golgi-Cox stained neurons showed that apomorphine reduced the total length of dendrites in the CA1 region of the hippocampus. Finally, there were more reactive astrocytes and oxidative stress biomarkers in mice administered apomorphine, as measured by GFAP immunohistochemistry and markers of redox balance, respectively. Hence, the non-selective activation of dopaminergic receptors in the hippocampus by apomorphine triggers deficiencies in learning and memory, it prevents LTP, reduces dendritic length, and provokes neuronal damage.

The effects of amphetamine exposure on juvenile rats on the neuronal morphology of the limbic system at prepubertal, pubertal and postpubertal ages.
Amphetamines (AMPH) are psychostimulants widely used for therapy as well as for recreational purposes. Previous results of our group showed that AMPH exposure in pregnant rats induces physiological and behavioral changes in the offspring at prepubertal and postpubertal ages. In addition, several reports have shown that AMPH are capable of modifying the morphology of neurons in some regions of the limbic system. These modifications can cause some psychiatric conditions. However, it is still unclear if there are changes to behavioral and morphological levels when low doses of AMPH are

administered at a juvenile age. The aim of this study was to assess the effect of AMPH administration (1mg/kg) in Sprague-Dawley rats (postnatal day, PD21-PD35) on locomotor activity in a novel environment and compare the neuronal morphology of limbic system areas at three different ages: prepubertal (PD 36), pubertal (PD50) and postpubertal (PD 62). We found that AMPH altered locomotor activity in the prepubertal group, but did not have an effect on the other two age groups. The Golgi-Cox staining method was used to describe the neural morphology of five limbic regions: (Layers 3 and 5) the medial prefrontal cortex (mPFC), the dorsal and ventral hippocampus, the nucleus accumbens and the amygdala, showing that AMPH induced changes at pubertal ages in arborization and spine density of these neurons, but interestingly these changes did not persist at postpubertal ages. Our findings suggest that even early-life AMPH exposure does not induce long-term behavioral and morphological changes, however it causes alterations at pubertal ages in the limbic system networks, a stage of life strongly associated with the development of substance abuse behaviors.

Combined administration of cerebrolysin and donepezil induces plastic changes in prefrontal cortex in aged mice. Cerebrolysin (Cbl) shows neurotrophic and neuroprotective properties while donepezil (Dnp) is a potent acetylcholinesterase (AChE) inhibitor, both drugs are prescribed for Alzheimer's disease (AD) treatment. Previous studies have shown that the Dnp and Cbl administered separately, modify dendritic morphology of neurons in the prefrontal cortex and hippocampus in senile rodents. Since the deficit of neurotrophic factor activity is implicated in the degeneration of cholinergic neurons of basal forebrain, a combination therapy of Dnp and Cbl has been tested recently in Alzheimer's patients. However, the plastic changes that may underlie this combined treatment have not yet been explored. We present here the effect of the combined administration of Cbl and Dnp on dendritic morphology in brain regions related to learning and memory in aged mice. The Golgi-Cox staining protocol and Sholl analysis were used for studying dendritic changes. Cbl and Dnp were administrated daily for 2 months to 9-months-old mice. Locomotor activity was assessed, as well as the dendritic morphology of neurons in several limbic regions was analyzed. Results showed that Cbl and Dnp induced an increase in locomotor activity without synergistic effect. The Cbl or Dnp treatment modified the dendritic morphology of neurons from prefrontal cortex (PFC), dorsal hippocampus (DH), dentate gyrus (DG), and the shell of nucleus accumbens (NAcc). These changes show an increase in the total dendritic length and spine density, resulting in an improvement of dendritic arborization. Prominently, a synergistic effect of Cbl and Dnp was observed on branching order and total dendritic length of pyramidal neurons from PFC. These results suggest that Dnp and Cbl may induce plastic changes in a manner independent of each other, but could enhance their effect in target cells from PFC.

DECIPHERING THE ROLE OF LOCUS COERULEUS FOR HIPPOCAMPUS-DEPENDENT LEARNING AND ITS IMPAIRMENT IN A MOUSE MODEL OF ALZHEIMER´S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Hanna Khomyak[1], Stefanie Poll[2], Martin Fuhrmann[1]
[1]DZNE, Bonn, Bonn, Germany, [2]University Hospital Bonn, Institute Of Experimental Epileptology And Cognition Research (ieecr), Bonn, Germany

Locus Coeruleus (LC) is a neuromodulatory system that is heavily and early affected during Alzheimer´s Disease (AD). The key goals of this project are to examine the influence of the LC on hippocampus (HPC)-dependent mnemonic processes and to study how such mnemonic processes are impaired in AD. First, we explored whether the structural and functional connectivity between the LC and the HPC is altered in a mouse model of AD-like pathology. A structural analysis of LC-HPC projections was performed by establishing an AAV-mediated neural tracing protocol. For the functional analysis of these projections, we will use *in vivo* two-photon Ca^{2+} imaging. Specifically, we will record axonal projections in hippocampal CA1 that originate from the LC while the mouse is moving on a treadmill performing tasks designed to test spatial and working memory. We will use transgenic mouse models that exhibit hallmarks of AD-pathology, namely APPswe/PSEN1dE9 (Plaque-pathology) and P301S mice (Tau-pathology). First results indicate that employing the AAV-mediated neural tracing protocol allows specific tracing of axonal connections between the LC and CA1. Furthermore, we found axonal dystrophies of LC-originating neurites in the HPC of APPswe/PSEN1dE9 mice. Our results suggest that impaired mnemonic processing in AD might underlie defective LC-HPC connectivity. We expect to gain further insights about potential morphological and functional impairments of LC-HPC projections in mouse models of AD-like pathology to then pinpoint the functional significance of LC-HPC connectivity for hippocampus-dependent learning and memory.

Network dysfunction and hyperexcitability due to disruption of $GABA_A$-mediated transmission during early stages of Alzheimer's disease (AD) are postulated to underlie AD-associated cognitive deficits. While disrupted $GABA_A$ signaling may result from several mechanisms, recent evidence points to deficits in the potassium-chloride cotransporter KCC2, responsible for maintaining low intracellular chloride in neurons to maintain robust inhibition. Thus, we tested whether impaired KCC2 function and disrupted chloride transport underlie these cognitive deficits. In both the multi-mutation transgenic 5xFAD mice and the amyloid precursor protein knock-in APP^{NL-G-F} mice we found a decrease in membrane protein levels of KCC2 in layer II/III of the prefrontal cortex and the CA1 region of the hippocampus as compared to their non-transgenic (NonTg) age-matched littermates. In addition, *ex vivo* chloride imaging revealed weakened Cl^- transport in the 5xFAD mice while *in vivo* chloride imaging revealed that the distribution of $[Cl^-]i$ in pyramidal neurons from 5xFAD mice was significantly lower than in NonTg mice. Finally, short-term administration of CLP290, a KCC2 enhancer developed by our laboratory, in the 5xFAD mice improved spatial memory retention in the Morris Water Task (MWT) and social interaction deficits as compared to vehicle-treated mice, while long-term treatment with CLP290 augmented learning performance in the MWT. All together, these results indicate that KCC2 may be a viable target for reversing deficits in $GABA_A$-mediated inhibition in AD and attenuating cognitive deficits in mice carrying AD-linked mutations.

A Wireless Electro-Optic Platform for Multimodal Electrophysiology and Optogenetics in Freely Moving Rodents.
This paper presents the design and the utilization of a wireless electro-optic platform to perform simultaneous multimodal electrophysiological recordings and optogenetic stimulation in freely moving rodents. The developed system can capture neural action potentials (AP), local field potentials (LFP) and electromyography (EMG) signals with up to 32 channels in parallel while providing four optical stimulation channels. The platform is using commercial off-the-shelf components (COTS) and a low-power digital field-programmable gate array (FPGA), to perform digital signal processing to digitally separate in real time the AP, LFP and EMG while performing signal detection and compression for mitigating wireless bandwidth and power consumption limitations. The different signal modalities collected on the 32 channels are time-multiplexed into a single data stream to decrease power consumption and optimize resource utilization. The data reduction strategy is based on signal processing and real-time data compression. Digital filtering, signal detection, and wavelet data compression are used inside the platform to separate the different electrophysiological signal modalities, namely the local field potentials (1-500 Hz), EMG (30-500 Hz), and the action potentials (300-5,000 Hz) and perform data reduction before transmitting the data. The platform achieves a measured data reduction ratio of 7.77 (for a firing rate of 50 AP/second) and weights 4.7 g with a 100-mAh battery, an on/off switch and a protective plastic enclosure. To validate the performance of the platform, we measured distinct electrophysiology signals and performed optogenetics stimulation in freely moving rondents. We recorded AP and LFP signals with the platform using a 16-microelectrode array implanted in the primary motor cortex of a Long Evans rat, both in anesthetized and freely moving conditions. EMG responses to optogenetic Channelrhodopsin-2 induced activation of motor cortex optical fiber were also recorded in freely moving rodents.

Functional Interactions of Tau Phosphorylation Sites That Mediate Toxicity and Deficient Learning in .
Hyperphosphorylated Tau protein is the main component of the neurofibrillary tangles, characterizing degenerating neurons

in Alzheimer's disease and other Tauopathies. Expression of human Tau protein in Drosophila CNS results in increased toxicity, premature mortality and learning and memory deficits. Herein we use novel transgenic lines to investigate the contribution of specific phosphorylation sites previously implicated in Tau toxicity. These three different sites, Ser, Thr, and Ser were tested either by blocking their phosphorylation, by Ser/Thr to Ala substitution, or pseudophosphorylation, by changing Ser/Thr to Glu. We validate the hypothesis that phosphorylation at Ser is necessary for Tau-dependent learning deficits and a "facilitatory gatekeeper" to Ser occupation, which is linked to Tau toxicity. Importantly we reveal that phosphorylation at Thr acts as a "suppressive gatekeeper", preventing phosphorylation of many sites including Ser and consequently of Ser. Therefore, we elucidate novel interactions among phosphosites central to Tau mediated neuronal dysfunction and toxicity, likely driven by phosphorylation-dependent conformational plasticity.

Cortical interneuron-mediated inhibition delays the onset of amyotrophic lateral sclerosis.
Amyotrophic lateral sclerosis is a fatal disease resulting from motor neuron degeneration in the cortex and spinal cord. Cortical hyperexcitability is a hallmark feature of amyotrophic lateral sclerosis and is accompanied by decreased intracortical inhibition. Using electrophysiological patch-clamp recordings, we revealed parvalbumin interneurons to be hypoactive in the late pre-symptomatic SOD1*G93A mouse model of amyotrophic lateral sclerosis. We discovered that using adeno-associated virus-mediated delivery of chemogenetic technology targeted to increase the activity of the interneurons within layer 5 of the primary motor cortex, we were able to rescue intracortical inhibition and reduce pyramidal neuron hyperexcitability. Increasing the activity of interneurons in the layer 5 of the primary motor cortex was effective in delaying the onset of amyotrophic lateral sclerosis-associated motor deficits, slowing symptom progression, preserving neuronal populations, and increasing the lifespan of SOD1*G93A mice. Taken together, this study provides novel insights into the pathogenesis and treatment of amyotrophic lateral sclerosis.

A Wireless Electro-Optic Headstage With a 0.13- µm CMOS Custom Integrated DWT Neural Signal Decoder for Closed-Loop Optogenetics.
We present a wireless electro-optic headstage that uses a 0.13- µm CMOS custom integrated circuit (IC) implementing a digital neural decoder (ND-IC) for enabling real-time closed-loop (CL) optogenetics. The ND-IC processes the neural activity data using three digital cores: 1) the detector core detects and extracts the action potential (AP) of individual neurons by using an adaptive threshold; 2) the data compression core compresses the detected AP by using an efficient Symmlet-2 discrete wavelet transform (DWT) processor for decreasing the amount of data to be transmitted by the low-power wireless link; and 3) the classification core sorts the compressed AP into separated clusters on the fly according to their wave shapes. The ND-IC encompasses several innovations: 1) the compression core decreases the complexity from O(n) to O(n · log(n)) compared to the previous solutions, while using two times less memory, thanks to the use of a new coefficient sorting tree; and 2) the AP classification core reuses both the compressed DWT coefficients to perform implicit dimensionality reduction, which allows for performing intensive signal processing on-chip, while increasing power and hardware efficiency. This core also reuses the signal standard deviation already computed by the AP detector core as threshold for performing automatic AP sorting. The headstage also introduces innovations by enabling a new wireless CL scheme between the neural data acquisition module and the optical stimulator. Our CL scheme uses the AP sorting and timing information produced by the ND-IC for detecting complex firing patterns within the brain. The headstage is also smaller (1.13 cm), lighter (3.0 g with a 40 mAh battery) and less invasive than the previous solutions, while providing a measured autonomy of 2h40, with the ND-IC. The whole system and the ND-IC are first validated in vivo in the LD thalamus of a Long-Evans rat, and then in freely-moving CL experiments involving a mouse virally expressing ChR2-mCherry in inhibitory neurons of the prelimbic cortex, and the results show that our system works well within an in vivo experimental setting with a freely moving mouse.

Multiple pathologic mechanisms, including amyloid-β (Aβ) plaques, neurofibrillary tangles (NFTs), and neuroinflammation contribute to Alzheimer's disease (AD). How these affect progressive loss of long-term memory (LTM), the cardinal symptom of AD, is unclear. We have previously shown that persistent increases in PKMζ maintain LTP and LTM in wild-type hippocampal neurons, and that in PKMζ-null mice these functions are partially compensated by PKCι/λ. Here we hypothesize that this suboptimal compensation by PKCι/λ for PKMζ loss may be the basis of LTM disruption in AD. Using postmortem tissue from aged AD patients and matched controls, we find that PKMζ and PKCι/λ are present in a subset of NFTs within hippocampus, entorhinal cortex, subiculum, and amygdala (DOI:10.1097/01.jnen.0000218442.07664.04). Double-labeling with PHF1, which recognizes phosphorylated tau, confirms the presence of PKMζ in NFT-bearing neurons (Ibid.). In addition to abnormal accumulation in tangles, there is widespread reduction in PKMζ levels in all CA1 pyramidal cells. We then examined the effect of Aβ accumulation on the distribution of PKMζ and PKCι/λ in aged APP/PS1 mice. In line with previous reports that measured PKMζ by immunoblot (DOI:10.1038/nn.3486), quantitative immunohistochemistry revealed a dramatic downregulation of PKMζ in all layers of hippocampus and neocortex of 24-month-old APP/PS1 mice, compared to wild type littermates. In contrast, PKCι/λ was elevated, suggesting that downregulation of PKMζ by excess Aβ is suboptimally compensated, as in PKMζ-null mice. These results suggest that multiple pathophysiological mechanisms in AD dysregulate the core and suboptimal compensatory aPKC maintenance mechanisms within the neuronal ensembles that organize and encode LTM.

Alzheimer´s disease (AD) is characterized by a decline in cognitive and non-cognitive functions, including those mediated by limbic areas, such as the nucleus accumbens (nAc). Previous studies have shown the presence of inhibitory glycine receptors (GlyRs) in the nAc, whose activation is highly sensitive to ethanol. Furthermore, previous data using the APP/PS1 mice model (6-month-old), revealed decreased GlyRs expression and function in the nAc. Therefore, we hypothesize that GlyRs alterations in AD affect nAc functions and reward-related behaviors. For this, we examined calcium transients using the calcium fluorescent protein reporter GCaMP, performed electrical stimulation in nAc neurons and measured calcium transients by slice photometry. Increases in fluorescence was observed after addition of the GlyRs antagonist (strychnine 1 and 4 μM). However, the effect of strychnine in the APP/PS1 mice was significantly reduced. Using patch clamp technique in slices, we compared GlyRs function and ethanol potentiation. We found that ethanol potentiation was significantly decreased in AD mice. Finally, we performed drinking in the dark (DID) experiments and found that AD mice consumed significantly less ethanol in the last day of DID, consistent with lower blood ethanol concentration. Interestingly, we found that APP/PS1 mice also had lower sucrose consumption. Collectively, these data support the important role of GlyRs in nAc neuron excitability; and that decreased glycinergic activity in the APP/PS1 mice might lead to impairment in reward processing. THE ROLE OF INPUTS FROM HIPPOCAMPUS AND ENTORHINAL CORTEX TO THE PREFRONTAL CORTEX IN SPATIAL MEMORY IMPAIRMENTS IN A MOUSE MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Emine Ciftci[1,2], Eleonora Ambrad[2], Falko Fuhrmann[2], Manuel Mittag[2], Martin Fuhrmann[2], Stefanie Poll[1]
[1]University Hospital Bonn, Institute Of Experimental Epileptology And Cognition Research (ieecr), Bonn, Germany, [2]German Center for Neurodegenerative Diseases (DZNE), Neuroimmunology And Imaging, Bonn, Germany

Alzheimer´s disease (AD) is characterized by memory deficits including spatial working memory. The hippocampus (HPC) and the prefrontal cortex (PFC), most notably damaged by AD pathology, are relevant brain regions for spatial working memory. Though supporting distinct functions in memory processing, the HPC and the PFC are highly connected and operate in synergy to consolidate and retrieve memories. Specifically, the PFC is involved in top-down control of memory processing. Furthermore, both excitatory and long-range inhibitory projections between the HPC and PFC have been poorly characterized in disease-like conditions. In fact, it remains unknown whether structural and functional connectivity deficits between these brain areas are causally linked to spatial working memory deficits under AD-like conditions. Here, we investigated the structural and functional connectivity between these brain regions in a mouse model of AD-like pathology (APPswePSEN1dE9). We used a cell type-specific Cre-driver mouse line to target somatostatin (SST)-positive interneurons and AAV-mediated Cre-dependent fluorophore expression to conduct anterograde tracings. Moreover, we made use of microprism-based two-photon Ca^{2+} imaging in the PFC of awake, head-fixed mice, performing a spatial working memory task on a treadmill. Our first data show the accumulation of amyloid ß (Aß) plaques in the PFC and pathology-associated structural alterations of hippocampal axonal projections in the PFC. Interestingly, SST^{+} axonal projections were also affected by amyloidosis. These results indicate that structural connectivity impairments between HPC and PFC in a mouse model of AD-like pathology might underlie spatial working memory deficits.

Alzheimer disease (AD), the most frequent form of dementia is characterized by gradual cognitive decline, accumulation of Aβ-oligomers, progressive neuronal degeneration and chronic neuroinflammation. Among the first events in AD is the selective degeneration of cholinergic basal forebrain neurons characterized by their high expression levels of the p75 neurotrophin receptor ($p75^{NTR}$). Interestingly, $p75^{NTR}$ regulates several crucial processes in the adult brain, including neuronal survival, architecture and plasticity. Amongst other cell-surface proteins, $p75^{NTR}$ has been shown to bind soluble Aβ-oligomers and to mediate some of the toxic effects of Aβ on neurons. Moreover, $p75^{NTR}$ is expressed in microglia, where it is markedly increased under pathological conditions. These observations indicate $p75^{NTR}$ as a potential candidate for mediating the Aβ-induced phenotypes during AD. Here we use APP/PS1 transgenic mice and compare the Aβ-induced alterations in neuronal function, chronic inflammation as well as their cognitive consequences between 10 months old APP/PS1 and APP/PS1 $p75^{NTRExonIV}$ KO mice. Electrophysiological recordings show that a loss $p75^{NTR}$ rescues the impairment in long term potentiation observed at the Schaffer collaterals in the hippocampus of APP/PS1 mice. Interestingly, however loss of $p75^{NTR}$ does not influence the severity of neuroinflammation, microglia activation or the decline in spatial learning and memory processes observed in APP/PS1 transgenic mice. Current experiments address on one side the specific actions of $p75^{NTR}$ at synapses, possibly underlying the rescue of synaptic plasticity as well as the actions of $p75^{NTR}$ in modulating microglial function. MK and HD are funded by the Helmholtz-Gemeinschaft, Zukunftsthema ''Immunology and Inflammation'' (ZT-0027)

IMPACT OF ALZHEIMER'S DISEASE ON THE MORPHOLOGY OF HUMAN DENTATE GRANULE CELLS.

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Berenice Márquez-Valadez[1,2], Alberto Rábano[3], Maria Llorens-Martín[1,2]
[1]Center for Networked Biomedical Research on Neurodegenerative Diseases (CIBERNED), Enfermedad De Alzheimer Y Otras Demencias Degenerativas, Madrid, Spain, [2]Centro de Biología Molecular "Severo Ochoa" (CBMSO), Spanish Research Council (CSIC)–Universidad Autónoma de Madrid (UAM), Department Of Molecular Neuropathology, Madrid, Spain, [3]Centro en Investigación de Enfermedades Neurológicas, CIEN Foundation, Neuropathology Department, Madrid, Spain

Aim: Alzheimer's disease (AD) is the most common form of dementia. The hippocampus is one of the most affected brain areas in patients with this disorder. In particular, remarkable alterations have been reported in pyramidal neurons of the CA1 and CA3 hippocampal subfields. However, the extent to which dentate granule cells (DGCs) are affected by AD progression remains to be fully elucidated. The general aim of this study was to address whether human DGCs show morphological alterations in patients with AD. **Methods:** Human hippocampal samples obtained from neurologically healthy control subjects and patients with AD (distributed among the 6 neuropathological Braak-Tau stages of the disease) were subjected to Golgi-cox staining using the rapid Golgi-stain kit. A total number of 639 DGCs were traced and reconstructed for morphological analysis. **Results:** Morphometric analyses revealed that the DGCs of AD patients show alterations in their soma area, dendritic branching (Sholl´s analysis), total dendritic length, number of branch-tips, number of primary apical dendrites, branching index, and dendritic span. Each of these alterations start to be observed at distinct Braak-Tau stages. **Conclusions:** Our results show that morphological alterations of human DGCs appear at early Braak-Tau stages and are maintained during the disease progression. These alterations may be related to certain types of cognitive impairments observed in AD patients.

The natural xanthone alpha-mangostin reduces oxidative damage in rat brain tissue.
The antiperoxidative properties of alpha-mangostin, a xanthone isolated from mangosteen fruit, were tested for the first time in nerve tissue exposed to different toxic insults. Two reliable biological preparations (rat brain homogenates and synaptosomal P2 fractions) were exposed to the toxic actions of a free radical generator (ferrous sulfate), an excitotoxic agent (quinolinate), and a mitochondrial toxin (3-nitropropionate). alpha-Mangostin decreased the lipoperoxidative action of FeSO(4) in both preparations in a concentration-dependent manner, and completely abolished the peroxidative effects of quinolinate, 3-nitropropionate and FeSO(4) + quinolinate at all concentrations tested. Interestingly, when tested alone in brain homogenates, alpha-mangostin significantly decreased the lipoperoxidation even below basal levels. alpha-Mangostin also prevented the decreased reductant capacity of mitochondria in synaptosomal fractions. Our results suggest that alpha-mangostin exerts a robust antiperoxidative effect in brain tissue preparations probably through its properties as a free radical scavenger. In light of these findings, this antioxidant should be tested in other neurotoxic models involving oxidative stress. Nutr Neurosci, 2009; 12

The protective role of heme oxygenase-1 in cerebral ischemia.
Cerebral ischemia is one of the leading causes of death and disability in industrialized countries, with no curative treatments to date. Identification of potential targets and elucidation of their physiological role under stress conditions may give support to the development of drugs and strategies to contend with this pathology. In the last years, Heme oxygenase-1 (HO-1) has been considered by many groups as a potential target in ischemic damage. HO-1 is the enzyme responsible for the conversion of the heme group to billiverdin, carbon monoxide and iron; a highly regulated cytoprotective enzyme able to respond to numerous chemical or physical stressors, many of which decrease oxygen availability and generate oxidative stress. The disruption of HO-1 activity has been widely associated with a bad outcome in many disorders, and a protective role through its heme catabolism products has been observed in transplantation, cardiac ischemia, limb ischemia/reperfusion

and different alterations that involve ischemia and reperfusion events. Here, we review recent reports supporting the protective role of HO-1 in cerebral ischemia. Results on the endogenous HO-1 response, overexpression of HO-1 and compounds that reduce ischemic damage through the induction of HO-1 in cerebral ischemia in in vivo and in vitro models are analyzed.

Early changes in oxidative stress markers in a rat model of acute stress: effect of l-carnitine on the striatum.
This work focuses on the effect of acute stress on different markers of oxidative stress and mitochondrial dysfunction in the rat striatum. In addition, the effect of a single dose of l-carnitine (l-CAR, 300 mg/kg, i.p.) was evaluated in these animals. Immobilization (restraint) stress was induced to rats for 24 hr. The levels of lipid peroxidation (LP) and mitochondrial function (MF), as well as the superoxide dismutase (SOD) activity and content and reduced glutathione (GSH) levels, were all measured in striatal samples of animals subjected to stress. Our results indicate that acute stress is able to increase the striatal LP and reduced the levels of MF, while significantly lowered the manganese superoxide dismutase (Mn-SOD) activity. No changes were observed in the total striatal content of SOD, nor in GSH levels, but serum corticosterone content was increased by stress. l-CAR exhibited partial protective effects on the immobilized group, reducing the striatal LP and recovering the striatal MF and Mn-SOD activity. Our results suggest that acute restraint stress brings an accurate model for early pro-oxidant responses that can be targeted by broad-spectrum antioxidants like l-CAR.

Diazepam blocks striatal lipid peroxidation and improves stereotyped activity in a rat model of acute stress.
In this work, the effect of a single dose of diazepam was tested on different markers of oxidative damage in the striatum of rats in an acute model of immobilization (restraint) stress. In addition, the locomotor activity was measured at the end of the restraint period. Immobilization was induced to animals for 24 hr, and then, lipid peroxidation, superoxide dismutase activity and content, and mitochondrial function were all estimated in striatal tissue samples. Corticosterone levels were measured in serum. Diazepam was given to rats as a pre-treatment (1 mg/kg, i.p.) 20 min. before the initiation of stress. Our results indicate that acute stress produced enhanced striatal levels of lipid peroxidation (73% above the control), decreased superoxide dismutase activity (54% below the control), reduced levels of mitochondrial function (35% below the control) and increased corticosterone serum levels (86% above the control). Pre-treatment of stressed rats with diazepam decreased the striatal lipid peroxidation levels (68% below the stress group) and improved mitochondrial function (18% above the stress group), but only mild preservation of superoxide dismutase activity was detected (17% above the stress group). In regard to the motor assessment, only the stereotyped activity was increased in the stress group with respect to control (46% above the control), and this effect was prevented by diazepam administration (30% below the stress group). The preventive actions of diazepam in this acute model of stress suggest that drugs exhibiting anxiolytic and antioxidant properties might be useful for the design of therapies against early acute phases of physic stress.

Green tea compound epigallo-catechin-3-gallate (EGCG) increases neuronal survival in adult hippocampal neurogenesis in vivo and in vitro.
Epigallo-catechin-3-gallate (EGCG), found in the leaves of Camellia sinensis (green tea), has antioxidant- and scavenger-functions and acts neuroprotectively. It has been publicized as anti-aging remedy but data on potential cellular mechanisms are scarce. Recent studies claimed that EGCG specifically promotes neural precursor cell proliferation in the dentate gyrus of C57Bl/6 mice, without changes at the level of immature and mature new neurons. We here analyzed the effects of EGCG on adult hippocampal neurogenesis in male Balb/C mice and saw a different pattern. Two weeks of treatment with EGCG (0, 0.625, 1.25, 2.5, 5 and 10mg/kg) showed a dose-response curve that peaked at 2.5mg/kg of EGCG with significantly increased cell survival without affecting cell proliferation but decreasing apoptotic cells. Also, EGCG increased the population

of doublecortin-(DCX)-expressing cells that comprises the late intermediate progenitor cells (type-2b and -3) as well as immature neurons. After EGCG treatment, the young DCX-positive neurons showed more elaborated dendritic trees. EGCG also significantly increased net neurogenesis in the adult hippocampus and increased the hippocampal levels of phospho-Akt. Ex vivo, EGCG exerted a direct effect on survival and neuronal differentiation of adult hippocampal precursor cells, which was absent, when PI3K, a protein upstream of Akt, was blocked. Our results thus support a pro-survival and a pro-neurogenic role of EGCG. In the context of the conflicting published results, however, potential genetic modifiers must be assumed. These might help to explain the overall variability of study results with EGCG. Our data do indicate, however, that natural compounds such as EGCG can in principle modulate brain plasticity.

Maternal Diabetes and Fetal Programming Toward Neurological Diseases: Beyond Neural Tube Defects.
The purpose of this review was to search for experimental or clinical evidence on the effect of hyperglycemia in fetal programming to neurological diseases, excluding evident neural tube defects. The lack of timely diagnosis and the inadequate control of diabetes during pregnancy have been related with postnatal obesity, low intellectual and verbal coefficients, language and motor deficits, attention deficit with hyperactivity, problems in psychosocial development, and an increased predisposition to autism and schizophrenia. It has been proposed that several childhood or adulthood diseases have their origin during fetal development through a phenomenon called fetal programming. However, not all the relationships between the outcomes mentioned above and diabetes during gestation are clear, well-studied, or have been related to fetal programming. To understand this relationship, it is imperative to understand how developmental processes take place in health, in order to understand how the functional cytoarchitecture of the central nervous system takes place; to identify changes prompted by hyperglycemia, and to correlate them with the above postnatal impaired functions. Although changes in the establishment of patterns during central nervous system fetal development are related to a wide variety of neurological pathologies, the mechanism by which several maternal conditions promote fetal alterations that contribute to impaired neural development with postnatal consequences are not clear. Animal models have been extremely useful in studying the effect of maternal pathologies on embryo and fetal development, since obtaining central nervous system tissue in humans with normal appearance during fetal development is an important limitation. This review explores the state of the art on this topic, to help establish the way forward in the study of fetal programming under hyperglycemia and its impact on neurological and psychiatric disorders.

The Systemic Administration of the Histamine H Receptor Antagonist/Inverse Agonist Chlorpheniramine to Pregnant Rats Impairs the Development of Nigro-Striatal Dopaminergic Neurons.
The dopaminergic and histaminergic systems are the first to appear during the development of the nervous system. Through the activation of H receptors (HRs), histamine increases neurogenesis of the cortical deep layers, while reducing the dopaminergic phenotype (cells immunoreactive to tyrosine hydroxylase, TH) in embryo ventral mesencephalon. Although the function of histamine in neuronal differentiation has been studied, the role of HRs in neurogenesis has not been addressed. For this purpose, the HR antagonist/inverse agonist chlorpheniramine was systemically administered (5 mg/kg, i.p.) to pregnant Wistar rats (gestational days 12-14, E12-14), and control and experimental embryos (E14 and E16) and pups (21-day-old) were evaluated for changes in nigro-striatal development. Western blot and immunohistochemistry determinations showed a significant increase in the dopaminergic markers' TH and PITX3 in embryos from chlorpheniramine-treated rats at E16. Unexpectedly, 21-day-old pups from the chlorpheniramine-treated group, showed a significant reduction in TH immunoreactivity in the substantia nigra and dorsal striatum. Furthermore, striatal dopamine content, evoked [H]-dopamine release and methamphetamine-stimulated motor activity were significantly lower compared to the control group. These results indicate that HR blockade at E14-E16 favors the differentiation of dopaminergic neurons, but hampers their migration, leading to a decrease in dopaminergic innervation of the striatum in post-natal life.
Front Neurosci, 2019; 13
33042999: Valle-Bautista R, Márquez-Valadez B, Fragoso-Cabrera AD, García-López G, Díaz NF, Herrera-López G, Griego E, Galván EJ, Arias-Montaño JA, Molina-Hernández A
Impaired Cortical Cytoarchitecture and Reduced Excitability of Deep-Layer Neurons in the Offspring of Diabetic Rats.
Maternal diabetes has been related to low verbal task scores, impaired fine and gross motor skills, and poor performance in graphic and visuospatial tasks during childhood. The primary motor cortex is important for controlling motor functions, and embryos exposed to high glucose show changes in cell proliferation, migration, and differentiation during corticogenesis. However, the existing studies do not discriminate between embryos with or without neural tube defects, making it difficult to conclude whether the reported changes are related to neural tube defects or other anomalies. Furthermore, postnatal effects

on central nervous system cytoarchitecture and function have been scarcely addressed. Through molecular, biochemical, morphological, and electrophysiological approaches, we provide evidence of impaired primary motor cerebral cortex lamination and neuronal function in pups from diabetic rats, showing an altered distribution of SATB2, FOXP2, and TBR1, impaired cell migration and polarity, and decreased excitability of deep-layer cortical neurons, suggesting abnormalities in cortico-cortical and extra-cortical innervation. Furthermore, phase-plot analysis of action potentials suggests changes in the activity of potassium channels. These results indicate that high-glucose insult during development promotes complex changes in migration, neurogenesis, cell polarity establishment, and dendritic arborization, which in turn lead to reduced excitability of deep-layer cortical neurons.
Front Cell Dev Biol, 2020; 8
35140581: Valle-Bautista R, Márquez-Valadez B, Herrera-López G, Griego E, Galván EJ, Díaz NF, Arias-Montaño JA, Molina-Hernández A
Long-Term Functional and Cytoarchitectonic Effects of the Systemic Administration of the Histamine H Receptor Antagonist/Inverse Agonist Chlorpheniramine During Gestation in the Rat Offspring Primary Motor Cortex.
The transient histaminergic system is among the first neurotransmitter systems to appear during brain development in the rat mesencephalon/rhombencephalon. Histamine increases FOXP2-positive deep-layer neuron differentiation of cortical neural stem cells through H receptor activation . The or systemic administration of chlorpheniramine (H receptor antagonist/inverse agonist) during deep-layer cortical neurogenesis decreases FOXP2 neurons in the developing cortex, and HR- or histidine decarboxylase-knockout mice show impairment in learning and memory, wakefulness and nociception, functions modulated by the cerebral cortex. Due to the role of HR in cortical neural stem cell neurogenesis, the purpose of this study was to evaluate the postnatal impact of the systemic administration of chlorpheniramine during deep-layer cortical neuron differentiation (E12-14) in the primary motor cortex (M1) of neonates (P0) and 21-day-old pups (P21). Chlorpheniramine or vehicle were systemically administered (5 mg/kg, i.p.) to pregnant Wistar rats at gestational days 12-14, and the expression and distribution of deep- (FOXP2 and TBR1) and superficial-layer (SATB2) neuronal cortical markers were analyzed in neonates from both groups. The qRT-PCR analysis revealed a reduction in the expression of Satb2 and FoxP2. However, Western blot and immunofluorescence showed increased protein levels in the chlorpheniramine-treated group. In P21 pups, the three markers showed impaired distribution and increased immunofluorescence in the experimental group. The Sholl analysis evidenced altered dendritic arborization of deep-layer neurons, with lower excitability in response to histamine, as evaluated by whole-cell patch-clamp recording, as well as diminished depolarization-evoked [H]-glutamate release from striatal slices. Overall, these results suggest long-lasting effects of blocking HRs during early neurogenesis that may impact the pathways involved in voluntary motor activity and cognition.

BOOSTING DOPAMINERGIC TRANSMISSION RESCUES HIPPOCAMPAL GABAERGIC ACTIVITY AND REDUCES EPILEPTIFORM ACTIVITY IN A MOUSE MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Elena Spoleti[1], Maria Luisa De Paolis[1], Livia La Barbera[1], Elena Possemato[1], Annalisa Nobili[1], Krashia Paraskevi[1], Marcello D'Amelio[2]
[1]Campus Bio-Medico University of Rome, Faculty Of Sciences And Technologies For Humans And Environment, Rome, Italy, [2]Campus Bio-Medico University of Rome, Faculty Of Medicine & Surgery, Rome, Italy

Epidemiological studies state that the risk of epilepsy is increased in Alzheimer's Disease (AD) patients, and patients suffering from epilepsy have an elevated risk to develop dementia. This puts hippocampal epileptiform activity in the center of attention in the study of both AD onset and progression. Epileptic-like seizures are related to network alterations and aberrant gamma oscillations - due to parvalbumin interneuron dysfunctions - all resulting in brain hyperexcitability. Although the basis of epileptiform activity are still unclear, evidence suggest that alterations in dopamine receptor levels might trigger brain hyperexcitability. Interestingly, clinical and experimental studies pinpoint the Ventral Tegmental Area (VTA) dopaminergic neurodegeneration as one of the first events in AD, raising the hypothesis that the consequent dopamine depletion could trigger early deficits. To investigate whether dopamine loss might affect network integrity, we focused on mechanisms underlying hippocampal hyperexcitability before, at the onset and after VTA neurodegeneration in the Tg2576 mouse model of AD. Our data reveal that, timely coincident with VTA degeneration, Tg2576 CA1 pyramidal neurons undergo increased epileptiform activity and reduced GABAergic inputs, due to decreased parvalbumin interneuron excitability. We also show a lower number of Tg2576 parvalbumin interneurons, associated with an impaired *p*-CREB expression, a transcription factor regulating various intracellular processes. Importantly, boosting dopaminergic transmission in Tg2576 mice rescues GABAergic tone onto CA1 pyramidal neurons, ameliorating hippocampal hyperexcitability. These results suggest that precocious and progressive VTA neurodegeneration and dopamine depletion may trigger hippocampal hyperexcitability, disclosing a possible mechanism leading to epileptiform activity in early AD.

Gradual decline in cognitive and non-cognitive functions are considered clinical hallmarks of Alzheimer's Disease (AD). Post-mortem autoptic analysis shows the presence of amyloid β deposits, neuroinflammation and severe brain atrophy. However, brain circuit alterations and cellular derailments, assessed in very early stages of AD, still remain elusive. The understanding of these early alterations is crucial to tackle defective mechanisms. In a previous study we proved that the Tg2576 mouse model of AD displays functional deficits in the dorsal hippocampus and relevant behavioural AD-related alterations. We had shown that these deficits in Tg2576 mice correlate with the precocious degeneration of dopamine (DA) neurons in the Ventral Tegmental Area (VTA) and can be restored by L-DOPA treatment. Due to the distinct functionality and connectivity of dorsal versus ventral hippocampus, here we investigated neuronal excitability and synaptic functionality in the ventral CA1 hippocampal sub-region of Tg2576 mice. We found an age-dependent alteration of cell excitability and firing in pyramidal neurons starting at 3 months of age, that correlates with reduced levels in the ventral CA1 of tyrosine hydroxylase - the rate-limiting enzyme of DA synthesis. Additionally, at odds with the dorsal hippocampus, we found no alterations in basal glutamatergic transmission and long-term plasticity of ventral neurons in 8-month old Tg2576 mice compared to age-matched controls. Last, we used computational analysis to model the early derailments of firing properties observed and hypothesize that the neuronal alterations found could depend on dysfunctional sodium and potassium conductances, leading to anticipated depolarization-block of action potential firing. The present study depicts that impairment of cell excitability and homeostatic control of firing in ventral CA1 pyramidal neurons is a prodromal feature in Tg2576 AD mice.

Nilotinib restores memory function by preventing dopaminergic neuron degeneration in a mouse model of Alzheimer's Disease.

What happens precociously to the brain destined to develop Alzheimer's Disease (AD) still remains to be elucidated and this is one reason why effective AD treatments are missing. Recent experimental and clinical studies indicate that the degeneration of the dopaminergic (DA) neurons in the Ventral Tegmental Area (VTA) could be one of the first events occurring in AD. However, the causes of the increased vulnerability of DA neurons in AD are missing. Here, we deeply investigate the physiology of DA neurons in the VTA before, at the onset, and after onset of VTA neurodegeneration. We use the Tg2576 mouse model of AD, overexpressing a mutated form of the human APP, to identify molecular targets that can be manipulated pharmacologically. We show that in Tg2576 mice, DA neurons of the VTA at the onset of degeneration undergo slight but functionally relevant changes in their electrophysiological properties and cell morphology. Importantly, these changes are associated with accumulation of autophagosomes, suggestive of a dysfunctional autophagy, and with enhanced activation of c-Abl, a tyrosine kinase previously implicated in the pathogenesis of neurodegenerative diseases. Chronic treatment of Tg2576 mice with Nilotinib, a validated c-Abl inhibitor, reduces c-Abl phosphorylation, improves autophagy, reduces Aβ levels and - more importantly - prevents degeneration as well as functional and morphological alterations in DA neurons of the VTA. Interestingly, the drug prevents the reduction of DA outflow to the hippocampus and ameliorates hippocampal-related cognitive functions. Our results strive to identify early pathological brain changes in AD, to provide a rational basis for new therapeutic interventions able to slow down the disease progression.

Resilience to anhedonia-passive coping induced by early life experience is linked to a long-lasting reduction of I current in VTA dopaminergic neurons.

Exposure to aversive events during sensitive developmental periods can affect the preferential coping strategy adopted by individuals later in life, leading to either stress-related psychiatric disorders, including depression, or to well-adaptation to future adversity and sources of stress, a behavior phenotype termed "resilience". We have previously shown that interfering with the development of mother-pups bond with the Repeated Cross Fostering (RCF) stress protocol can induce resilience to depression-like phenotype in adult C57BL/6J female mice. Here, we used patch-clamp recording in midbrain slice combined with both and pharmacology to test our hypothesis of a link between electrophysiological modifications of dopaminergic neurons in the intermediate Ventral Tegmental Area (VTA) of RCF animals and behavioral resilience. We found reduced hyperpolarization-activated (I) cation current amplitude and evoked firing in VTA dopaminergic neurons from both young and adult RCF female mice. , VTA-specific pharmacological manipulation of the I current reverted the pro-resilient phenotype in adult early-stressed mice or mimicked behavioral resilience in adult control animals. This is the first evidence showing how pro-resilience behavior induced by early events is linked to a long-lasting reduction of I current and excitability in VTA dopaminergic neurons.

THE SURVIVAL OF VTA DOPAMINE NEURONS IS ASSOCIATED WITH UPREGULATION OF CA2+ BINDING PROTEINS IN THE TG2576 MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Livia La Barbera[1,2], Annalisa Nobili[1], Emma Cauzzi[1], Ilaria Paoletti[1], Mauro Federici[2], Krashia Paraskevi[1], Marcello Melone[3], Flavio Keller[4], Nicola Biagio Mercuri[5], Fiorenzo Conti[3], Marcello D'Amelio[4]

In the last years clinical and experimental studies highlight the involvement of ventral tegmental area (VTA) dopaminergic neurons for early pathological alterations during Alzheimer's disease (AD) progression. In fact, recently we described a progressive degeneration of these neurons in the Tg2576 mouse model of AD, long before beta-amyloid plaque formation. Why VTA dopaminergic neurons are more vulnerable than others remains to be defined although we showed that their autophagy machinery is impaired precociously. Autophagy impairments could be the basis for accumulation of damaged mitochondria, leading to alterations in Ca^{2+} homeostasis and, ultimately, to functional/structural deterioration of VTA dopamine neurons. Indeed, deregulated Ca^{2+} homeostasis is linked with aging and neurodegeneration; thus, unravelling the mechanisms underlying Ca^{2+} buffering in dopaminergic neurons may lead to possible strategies to prevent or delay neuronal loss. Here, in the VTA dopaminergic neurons of Tg2576 mice, we found accumulation of swollen, damaged mitochondria, associated with translocation of the Apoptosis-inducing factor from the mitochondrial inner membrane to the nucleus. These alterations coincide with functional changes in neuronal firing. Interestingly, although there is progressive loss of dopaminergic neurons containing Ca^{2+}-binding proteins (Calbindin-D28K, Calretinin), the surviving neurons show increased expression of these proteins when compared to dopamine neurons from control mice. Accordingly, Ca^{2+} microfluorometry revealed reduced free Ca^{2+} levels in Tg2576 neurons. Our results demonstrate that overexpression of Ca^{2+}-binding proteins in VTA dopaminergic neurons helps to survive neurodegeneration, increasing the ability of these neurons to buffer free Ca^{2+}, thus acting as a neuroprotective agent to reduce neuronal suffering.

KINDLING-INDUCED REACTIVATION OF IMMEDIATE EARLY GENES IS ASSOCIATED WITH INCREASED SEIZURE SEVERITY AND NEUROINFLAMMATION IN 5XFAD MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Alzheimer's disease (AD) is a neurodegenerative disease affecting 50 million people worldwide. There is increased prevalence of epilepsy in patients with AD, and the two diseases are thought to have a bi-directional association. This study aimed to understand the relationship between AD and seizure susceptibility and to characterise the molecular signature of epileptogenesis in the setting of AD. Transgenic 5xFAD mice (N=20) and WT littermates (N=22) underwent electrical amygdala kindling to induce epilepsy phenotype, or were treated as sham (electrode implantation without stimulation). Kindling rate, seizure severity and cognitive behavioural performance were compared across the kindled and sham 5xFAD and WT mice. The transcriptome (RNA-sequencing) of the hippocampal tissue was examined through differential expression analysis, followed by weighted gene coexpression network analysis (WGCNA). The 5xFAD mice showed increased susceptibility to kindling-induced seizures and had significantly longer and more severe seizures compared to WT littermates (p=0.0002). They also showed impaired spatial memory compared to WT group, as measured by the Y-maze test. Transcriptomic profiling and WGCNA identified modules of inflammatory and cellular stress-associated genes correlated with seizure severity and impaired spatial memory. Notably, a module of early immediate genes showed significant correlation with kindled-5xFAD group, but not the shams. The regulatory hub genes, pcdh8, BDNF, and Nptx2, are involved in synapse formation/maintenance in homeostatic conditions and their dysregulation leads to loss of dendritic spine density. We speculate that the inherent low expression level of these hub genes in 5xFAD may contribute to increased susceptibility to epileptogenesis and seizure-associated damage, and represent potential therapeutic targets.

Adenosine A_{2A} receptors (A_{2A}Rs), the target of caffeine, are found abnormally upregulated in neurons of AD patient's brains in correlation with the development of cognitive deficits. To get insights into the impact of A_{2A} dysregulation in AD, we evaluated the consequences of a neuronal A_{2A}R upsurge in a transgenic model of AD-like amyloidogenesis (APP/PS1dE9 mice). We crossed APP/PS1 mice with the transgenic TRE-A_{2A} strain, carrying the mouse A_{2A}R under the control of a Tet-responsive-element promoter. This led to four genotypic groups: WT, APP, WT/TRE-A_{2A} and APP/TRE-A_{2A}. At 3m of age, all the animals were bilaterally injected in the hippocampus with an AAV2/5-CBA-ttA, allowing the expression of ttA transactivator and then neuronal A_{2A}R upsurge in TRE-A_{2A} animals. At 6m of age, when APP/PS1 mice do not display deficits, behavioral evaluations revealed that neuronal A_{2A}R overexpression strongly worsens spatial memory impairments of APP animals. While that was not associated with significant change in amyloid burden or neuroinflammation, neuronal A_{2A}R upsurge favored the development of neuritic tau pathology. Mass spectrometry-based high-throughput proteomics identified modifications in the molecular profile of APP/TRE-A_{2A}. Gene ontology analysis revealed that most highly downregulated proteins were related to synaptic function. Immunohistochemistry and western blot analysis confirmed loss of pre and postsynaptic markers when neuronal A_{2A}R is upregulated in APP mice. These data support that pathological upregulation of A_{2A}R in neurons enhance synapse vulnerability to amyloid and is instrumental towards the decline of cognitive functions in AD.

INCREASED EXPRESSION AND ABERRANT ACTIVITY OF NEURONAL NITRIC OXIDE SYNTHASE ALTERS GLUTAMATERGIC CALCIUM SIGNALING IN ALZHEIMER'S DISEASE NEURONS

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Rachelle Balez[1], Claire Stevens[1], Kerstin Lenk[2], Greg Sutherland[3], Lezanne Ooi[1]

Nitric oxide (NO), produced by the calcium (Ca^{2+}) activated enzyme neuronal nitric oxide synthase (nNOS), functions as a second messenger and modulates glutamatergic Ca^{2+} signaling in neurons. Aberrant Ca^{2+} signaling occurs in Alzheimer's disease, including in sporadic AD (sAD), however, the contribution of nNOS activity and NO to this phenotype is not well understood. The aim of this study was to first quantify nNOS expression and NO levels in sAD and then assess the impact of inhibiting nNOS activity or scavenging NO on neuronal Ca^{2+} signaling. Quantification of nNOS expression using immunostaining and western blotting showed a significant increase in nNOS amount in both human *post-mortem* tissue ($p=0.004$) and induced pluripotent stem cell (iPSC) derived neurons ($p=0.005$), from sAD patients compared to healthy donors. This was observed in conjunction with significantly elevated levels of nitrite in sAD iPSC-derived neurons ($p<0.001$), quantified using the Griess assay as a downstream marker of NO. Live cell Ca^{2+} imaging demonstrated that inhibition of nNOS activity, or scavenging of endogenous NO, significantly decreased the glutamatergic Ca^{2+} response in healthy iPSC-derived neurons ($p<0.001$). In contrast, this modulatory effect was lost in the sAD neurons, although there was a decrease in the proportion of spontaneously signaling neurons, suggesting pathogenic modification of signaling receptors. In conclusion, the results of this study show that NO increases the Ca^{2+} response to glutamate in healthy neurons, however, it contributes to spontaneous Ca^{2+} signaling during sAD, highlighting the contribution of this second messenger to aberrant Ca^{2+} signaling phenotype during AD.

Neuroprotective effects of apigenin against inflammation, neuronal excitability and apoptosis in an induced pluripotent stem cell model of Alzheimer's disease.
Alzheimer's disease (AD) is one of the most prevalent neurodegenerative diseases, yet current therapeutic treatments are inadequate due to a complex disease pathogenesis. The plant polyphenol apigenin has been shown to have anti-inflammatory and neuroprotective properties in a number of cell and animal models; however a comprehensive assessment has not been performed in a human model of AD. Here we have used a human induced pluripotent stem cell (iPSC) model of familial and sporadic AD, in addition to healthy controls, to assess the neuroprotective activity of apigenin. The iPSC-derived AD neurons demonstrated a hyper-excitable calcium signalling phenotype, elevated levels of nitrite, increased cytotoxicity and apoptosis, reduced neurite length and increased susceptibility to inflammatory stress challenge from activated murine microglia, in comparison to control neurons. We identified that apigenin has potent anti-inflammatory properties with the ability to protect neurites and cell viability by promoting a global down-regulation of cytokine and nitric oxide (NO) release in inflammatory cells. In addition, we show that apigenin is able to protect iPSC-derived AD neurons via multiple means by reducing the frequency of spontaneous Ca(2+) signals and significantly reducing caspase-3/7 mediated apoptosis. These data demonstrate the broad neuroprotective action of apigenin against AD pathogenesis in a human disease model.

Getting to NO Alzheimer's Disease: Neuroprotection versus Neurotoxicity Mediated by Nitric Oxide.
Alzheimer's disease (AD) is a neurodegenerative disorder involving the loss of neurons in the brain which leads to progressive memory loss and behavioral changes. To date, there are only limited medications for AD and no known cure. Nitric oxide (NO) has long been considered part of the neurotoxic insult caused by neuroinflammation in the Alzheimer's brain. However, focusing on early developments, prior to the appearance of cognitive symptoms, is changing that perception.

This has highlighted a compensatory, neuroprotective role for NO that protects synapses by increasing neuronal excitability. A potential mechanism for augmentation of excitability by NO is via modulation of voltage-gated potassium channel activity (Kv7 and Kv2). Identification of the ionic mechanisms and signaling pathways that mediate this protection is an important next step for the field. Harnessing the protective role of NO and related signaling pathways could provide a therapeutic avenue that prevents synapse loss early in disease.

Neuroprotection of Neuro2a cells and the cytokine suppressive and anti-inflammatory mode of action of resveratrol in activated RAW264.7 macrophages and C8-B4 microglia.
Chronic inflammation is a hallmark of neurodegenerative disease and cytotoxic levels of nitric oxide (NO) and pro-inflammatory cytokines can initiate neuronal death pathways. A range of cellular assays were used to assess the anti-inflammatory and neuroprotective action of resveratrol using murine microglial (C8-B4), macrophage (RAW264.7) and neuronal-like (Neuro2a) cell lines. We examined the release of NO by Griess assay and used a Bioplex array to measure a panel of pro- and anti-inflammatory cytokines and chemokines, in response to the inflammatory stimuli lipopolysaccharide (LPS) and interferon-γ (IFN-γ). Resveratrol was a potent inhibitor of NO and cytokine release in activated macrophages and microglia. The activity of resveratrol increased marginally in potency with longer pre-incubation times in cell culture that was not due to cytotoxicity. Using an NO donor we show that resveratrol can protect Neuro2a cells from cytotoxic concentrations of NO. The protective effect of resveratrol from pro-inflammatory signalling in RAW264.7 cells was confirmed in co-culture experiments leading to increased survival of Neuro2a cells. Together our data are indicative of the potential neuroprotective effect of resveratrol during nitrosative stress and neuroinflammation.

Identification and High-Resolution Imaging of α-Tocopherol from Human Cells to Whole Animals by TOF-SIMS Tandem Mass Spectrometry.
A unique method for identification of biomolecular components in different biological specimens, while preserving the capability for high speed 2D and 3D molecular imaging, is employed to investigate cellular response to oxidative stress. The employed method enables observing the distribution of the antioxidant α-tocopherol and other molecules in cellular structures via time-of-flight secondary ion mass spectrometry (TOF-SIMS (MS)) imaging in parallel with tandem mass spectrometry (MS) imaging, collected simultaneously. The described method is employed to examine a network formed by neuronal cells differentiated from human induced pluripotent stem cells (iPSCs), a model for investigating human neurons in vitro. The antioxidant α-tocopherol is identified in situ within different cellular layers utilizing a 3D TOF-SIMS tandem MS imaging analysis. As oxidative stress also plays an important role in mediating inflammation, the study was expanded to whole body tissue sections of M. marinum-infected zebrafish, a model organism for tuberculosis. The TOF-SIMS tandem MS imaging results reveal an increased presence of α-tocopherol in response to the pathogen. Graphical Abstract .

The mRNA-based reprogramming of fibroblasts from a SOD1 familial amyotrophic lateral sclerosis patient to induced pluripotent stem cell line UOWi007.
Dermal fibroblasts were donated by a 43 year old male patient with clinically diagnosed familial amyotrophic lateral sclerosis (ALS), carrying the SOD1 mutation. The induced pluripotent stem cell (iPSC) line UOWi007-A was generated using repeated mRNA transfections for pluripotency transcription factors Oct4, Klf4, Sox2, c-Myc, Lin28 and Nanog. The iPSCs carried the SOD1 genotype and had a normal karyotype, expressed expected pluripotency markers and were capable of in vitro differentiation into endodermal, mesodermal and ectodermal lineages. This iPSC line may be useful for investigating familial ALS resulting from a SOD1 mutation.

A Simple Differentiation Protocol for Generation of Induced Pluripotent Stem Cell-Derived Basal Forebrain-Like Cholinergic Neurons for Alzheimer's Disease and Frontotemporal Dementia Disease Modeling.
The study of neurodegenerative diseases using pluripotent stem cells requires new methods to assess neurodevelopment and neurodegeneration of specific neuronal subtypes. The cholinergic system, characterized by its use of the neurotransmitter acetylcholine, is one of the first to degenerate in Alzheimer's disease and is also affected in frontotemporal dementia. We developed a differentiation protocol to generate basal forebrain-like cholinergic neurons (BFCNs) from induced pluripotent stem cells (iPSCs) aided by the use of small molecule inhibitors and growth factors. Ten iPSC lines were successfully differentiated into BFCNs using this protocol. The neuronal cultures were characterised through RNA and protein expression, and functional analysis of neurons was confirmed by whole-cell patch clamp. We have developed a reliable protocol using only small molecule inhibitors and growth factors, while avoiding transfection or cell sorting methods, to achieve a BFCN culture that expresses the characteristic markers of cholinergic neurons.

The Ubiquitin Proteasome System Is a Key Regulator of Pluripotent Stem Cell Survival and Motor Neuron Differentiation.
The ubiquitin proteasome system (UPS) plays an important role in regulating numerous cellular processes, and a dysfunctional UPS is thought to contribute to motor neuron disease. Consequently, we sought to map the changing ubiquitome in human iPSCs during their pluripotent stage and following differentiation to motor neurons. Ubiquitinomics analysis identified that spliceosomal and ribosomal proteins were more ubiquitylated in pluripotent stem cells, whilst proteins involved in fatty acid metabolism and the cytoskeleton were specifically ubiquitylated in the motor neurons. The UPS regulator, ubiquitin-like modifier activating enzyme 1 (UBA1), was increased 36-fold in the ubiquitome of motor neurons compared to pluripotent stem cells. Thus, we further investigated the functional consequences of inhibiting the UPS and UBA1 on motor neurons. The proteasome inhibitor MG132, or the UBA1-specific inhibitor PYR41, significantly decreased the viability of motor neurons. Consistent with a role of the UPS in maintaining the cytoskeleton and regulating motor neuron differentiation, UBA1 inhibition also reduced neurite length. Pluripotent stem cells were extremely sensitive to MG132, showing toxicity at nanomolar concentrations. The motor neurons were more resilient to MG132 than pluripotent stem cells but demonstrated higher sensitivity than fibroblasts. Together, this data highlights the important regulatory role of the UPS in pluripotent stem cell survival and motor neuron differentiation.

SYNAPTOME ARCHITECTURE OF THE HUMAN HIPPOCAMPUS IS PROGRESSIVELY AND SPATIALLY ALTERED IN ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Zhen Qiu[1], Olimpia Curran[1,2], Colin Smith[1], Seth Grant[1]
[1]University of Edinburgh, Centre For Clinical Brain Sciences, Edinburgh, United Kingdom, [2]Cellular Pathology, University Hospital Of Wales, Cardiff, United Kingdom

Excitatory synapse loss is thought to underlie the cognitive impairments in Alzheimer's disease (AD). The development of molecular imaging methods that measure the protein composition and morphological parameters of billions of individual synapses in mouse brain has revealed very high synapse diversity described by the synaptome (Zhu et al, 10.1016/j.neuron.2018.07.007; Cizeron et al, 10.1126/science.aba3163). Here we report the synaptome mapping developed for human hippocampal formation (HPF), a key structure for learning and a locus of AD pathology. Excitatory synapses were fluorescently labelled using antibodies to PSD95, an abundant postsynaptic scaffold protein, then imaged with diffraction-limited resolution on a high-throughput spinning disk confocal microscope. Images including billions of individual synaptic puncta were analysed using advanced deep-learning methods, providing a data-driven catalogue of excitatory synapse subtypes. Analysis of 16 subregions of the HPF in 17 control, 11 early-stage (Braak II) and 10 late-stage (Braak VI) AD cases revealed 7 excitatory synapse subtypes, each with a unique spatial and statistical distribution. Our results showed subtypes were differentially and progressively affected by AD in both local subregional density and diversity and global HPF network topology, with some being resilient and others vulnerable at different stages of disease progression. The loss of vulnerable subtypes correlated with changes in Aβ deposition. Our synaptome map in the human hippocampus provides a multiscale reference resource for this key brain region and a baseline for neuropathological studies. Identification of vulnerable and resilient subtypes of excitatory synapses may suggest new diagnostic and therapeutic approaches in AD and other synaptopathies.

Jebsen Centre for Alzheimer's Disease, Norwegian University Of Science And Technology, Trondheim, Norway

Alzheimer's disease (AD) is a progressive and ultimately fatal disease. Early in the disease-process, circuits of the entorhinal-hippocampal memory system are lost. Among the first neurons to degenerate are reelin positive entorhinal cortex layer II (Re+ ECLII) neurons, which provide the main LII-projection to the hippocampus. Here we micro-dissect Re+ ECLII-neurons along with populations of hippocampal neurons from adult AD model animals and allow the neurons to re-form relevant connections within an *in vitro* environment, enabling the study of very early AD-relevant pathology within this *in vitro* circuit. We use adult animals of the APP/PS1 mouse model and the McGill-R-Thy1-APP rat model. From these model animals we micro-dissect and culture adult Re+ ECLII-neurons, DG granular neurons, CA3 pyramidal neurons and CA1 pyramidal neurons. Separate populations are cultured in separate chambers in a microfluidic chip-setup, with each chamber connected by one-way micro tunnels to allow for re-growth of axons in an anatomically relevant pattern. The microfluidic chip platform was either interfaced with microelectrode arrays to enable electrophysiological recordings or on glass slips for characterization by immunocytochemistry. Ongoing experiments show viability of the entorhinal-hippocampal cultures beyond 4 weeks. Structural connections form after 3 days *in vitro* and electrophysiological spikes are detected after 15 days *in vitro*.

CHARACTERISATION OF IN VIVO SYNAPTIC AND NEURONAL PHYSIOLOGY IN EARLY AND PROGRESSED AMYLOIDOPATHY (APP/PS1 MOUSE MODEL)

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Soraya Meftah, Jian Gan
University of Edinburgh, Uk Dementia Research Institute, Edinburgh, United Kingdom

The amyloid hypothesis suggests that abnormal accumulation of amyloid-beta is a key pre-symptomatic feature in Alzheimer's Disease, eventually leading to cognitive decline. Therefore, determining the effect of soluble and aggregated amyloid-beta on function is critical for the mechanistic understanding of Alzheimer's Disease pathophysiology. Phenotypes observed in models of amyloidopathy include neuronal hyperexcitability and altered excitation/inhibition balance, which are thought to promote network abnormalities. However, how amyloid-beta explicitly alters neuronal, and subthreshold synaptic transmission properties *in vivo*, and how this links to network activity in a computing brain, is still largely unknown. **Aims:** Characterise synaptic, neuronal, and network function at two ages (2-3 months and 6-10 months) in the APP/PS1 model of amyloidopathy to understand the effects of soluble and aggregated amyloid-beta on neurophysiology *in vivo*. **Methods:** *In vivo* whole-cell patch-clamp electrophysiology was used to record from putative pyramidal neurons in the CA1 of the hippocampus in the established $APP_{swe}/PS1_{\Delta E9}$ (APP/PS1) model of amyloidopathy and littermate controls. Simultaneous local field potential recordings were made adjacent to the whole-cell electrode. Basal spontaneous excitatory and inhibitory synaptic transmission was measured. Intrinsic properties and neuronal excitability were also characterised. **Results:** Results from this work will reveal how different disease phases of amyloidopathy can alter synaptic and neuronal function. These changes will be explored in relation to different network oscillations. **Conclusions:** This work will provide a mechanistic understanding of how synaptic, neuronal, and network phenotypes emerge and progress with the appearance of amyloid plaques. This will highlight potential targets of asymptomatic dysfunction in Alzheimer's Disease.

Tissue magnetic susceptibility mapping as a marker of tau pathology in Alzheimer's disease.
Alzheimer's disease is connected to a number of other neurodegenerative conditions, known collectively as 'tauopathies', by the presence of aggregated tau protein in the brain. Neuroinflammation and oxidative stress in AD are associated with tau pathology and both the breakdown of axonal sheaths in white matter tracts and excess iron accumulation grey matter brain regions. Despite the identification of myelin and iron concentration as major sources of contrast in quantitative susceptibility maps of the brain, the sensitivity of this technique to tau pathology has yet to be explored. In this study, we perform Quantitative Susceptibility Mapping (QSM) and T2* mapping in the rTg4510, a mouse model of tauopathy, both in vivo and ex vivo. Significant correlations were observed between histological measures of myelin content and both mean regional magnetic susceptibility and T2* values. These results suggest that magnetic susceptibility is sensitive to tissue myelin concentrations across different regions of the brain. Differences in magnetic susceptibility were detected in the corpus callosum, striatum, hippocampus and thalamus of the rTg4510 mice relative to wild type controls. The concentration of neurofibrillary tangles was found to be low to intermediate in these brain regions indicating that QSM may be a useful biomarker for early stage detection of tau pathology in neurodegenerative diseases.

Tracking progressive pathological and functional decline in the rTg4510 mouse model of tauopathy.
The choice and appropriate use of animal models in drug discovery for Alzheimer's disease (AD) is pivotal to successful clinical translation of novel therapeutics, yet true alignment of research is challenging. Current models do not fully recapitulate the human disease, and even exhibit various degrees of regional pathological burden and diverse functional alterations. Given this, relevant pathological and functional endpoints must be determined on a model-by-model basis. The present work explores the rTg4510 mouse model of tauopathy as a case study to define best practices for the selection and validation of

cognitive and functional endpoints for the purposes of pre-clinical AD drug discovery.

The inappropriate occurrence of rapid eye movement sleep in narcolepsy is not due to a defect in homeostatic regulation of rapid eye movement sleep.
Narcolepsy type 1 is a disabling disorder with four primary symptoms: excessive-daytime-sleepiness, cataplexy, hypnagogic hallucinations, and sleep paralysis. The later three symptoms together with a short rapid eye movement (REM) sleep latency have suggested impairment in REM sleep homeostatic regulation with an enhanced propensity for (i.e. tendency to enter) REM sleep. To test this hypothesis, we challenged REM sleep homeostatic regulation in a recognized model of narcolepsy, the orexin knock-out (Orex-KO) mice and their wild-type (WT) littermates. We first performed 48 hr of REM sleep deprivation using the classic small-platforms-over-water method. We found that narcoleptic mice are similarly REM sleep deprived to WT mice. Although they had shorter sleep latency, Orex-KO mice recovered similarly to WT during the following 10 hr of recovery. Interestingly, Orex-KO mice also had cataplexy episodes immediately after REM sleep deprivation, anticipating REM sleep rebound, at a time of day when cataplexy does not occur in baseline condition. We then evaluated REM sleep propensity using our new automated method of deprivation that performs a specific and efficient REM sleep deprivation. We showed that REM sleep propensity is similar during light phase in Orex-KO and WT mice. However, during the dark phase, REM sleep propensity was not suppressed in Orex-KO mice when hypocretin/orexin neuropeptides are normally released. Altogether our data suggest that in addition to the well-known wake-promoting role of hypocretin/orexin, these neuropeptides would also suppress REM sleep. Therefore, hypocretin/orexin deficiency would facilitate the occurrence of REM sleep at any time of day in an opportunistic manner as seen in human narcolepsy.

Impaired glymphatic function and clearance of tau in an Alzheimer's disease model.
The glymphatic system, that is aquaporin 4 (AQP4) facilitated exchange of CSF with interstitial fluid (ISF), may provide a clearance pathway for protein species such as amyloid-β and tau, which accumulate in the brain in Alzheimer's disease. Further, tau protein transference via the extracellular space, the compartment that is cleared by the glymphatic pathway, allows for its neuron-to-neuron propagation, and the regional progression of tauopathy in the disorder. The glymphatic system therefore represents an exciting new target for Alzheimer's disease. Here we aim to understand the involvement of glymphatic CSF-ISF exchange in tau pathology. First, we demonstrate impaired CSF-ISF exchange and AQP4 polarization in a mouse model of tauopathy, suggesting that this clearance pathway may have the potential to exacerbate or even induce pathogenic accumulation of tau. Subsequently, we establish the central role of AQP4 in the glymphatic clearance of tau from the brain; showing marked impaired glymphatic CSF-ISF exchange and tau protein clearance using the novel AQP4 inhibitor, TGN-020. As such, we show that this system presents as a novel druggable target for the treatment of Alzheimer's disease, and possibly other neurodegenerative diseases alike.

HIGH-RESOLUTION LOCAL AND GLOBAL MAPPING OF AMYLOID PLAQUE DEPOSITION PREDICTS BEHAVIOURAL AND COGNITIVE PERFORMANCE IN 5XFAD MOUSE MODELS OF ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Seigfred Prado, Mary Ann Go, Yimei Li, Beatriz Teixeira, Simon Schultz
Imperial College London, Bioengineering, London, United Kingdom

The 5xFAD mouse model of Alzheimer's Disease (AD) recapitulates many AD-related phenotypes and has a relatively early and aggressive presentation. In this model, extracellular amyloid plaques are seen in mice as young as two months of age. However, the degree to which the amyloid plaques affect behavioural and cognitive performances in this model is still not well known. Here we performed both *in vivo* and *ex vivo* high-resolution two-photon imaging to map the spatial distribution of Methoxy-X04-labelled amyloid plaques across age in 5xFAD mice. We collected two-photon calcium imaging data at the hippocampal CA1 region during spatial and working memory tasks and mapped the local distributions of amyloid plaques within this area. Given the locations of the cells being observed longitudinally during behavioural experiments, we quantified and correlated the statistical and morphological properties of amyloid plaque loads for every given spherical radius with the changes in neuronal activity properties and the behavioural performance of the mice. After termination, the brains were extracted, fixed and perfused in preparation for *ex vivo* whole-brain imaging. We used serial two-photon (STP) tomography to map the global distribution of amyloid plaques across the brain. Using a deep-learning U-Net architecture model, we automatically quantified plaque densities from each brain region and correlated these with the mice's behaviour. Our results demonstrate deficits in behavioural performance with region-specific progression of plaque load densities in critically affected brain structures. Hence, these models present an invaluable tool for early intervention and improved pre-clinical assessment of potential therapeutic approaches for AD.

Place Cells in Head-Fixed Mice Navigating a Floating Real-World Environment.
The hippocampal place cell system in rodents has provided a major paradigm for the scientific investigation of memory function and dysfunction. Place cells have been observed in area CA1 of the hippocampus of both freely moving animals, and of head-fixed animals navigating in virtual reality environments. However, spatial coding in virtual reality preparations has been observed to be impaired. Here we show that the use of a real-world environment system for head-fixed mice, consisting of an air-floating track with proximal cues, provides some advantages over virtual reality systems for the study of spatial memory. We imaged the hippocampus of head-fixed mice injected with the genetically encoded calcium indicator GCaMP6s while they navigated circularly constrained or open environments on the floating platform. We observed consistent place tuning in a substantial fraction of cells despite the absence of distal visual cues. Place fields remapped when animals entered a different environment. When animals re-entered the same environment, place fields typically remapped over a time period of multiple days, faster than in freely moving preparations, but comparable with virtual reality. Spatial information rates were within the range observed in freely moving mice. Manifold analysis indicated that spatial information could be extracted from a low-dimensional subspace of the neural population dynamics. This is the first demonstration of place cells in head-fixed mice navigating on an air-lifted real-world platform, validating its use for the study of brain circuits involved in memory and affected by neurodegenerative disorders.

MEMORY REACTIVATION DYNAMICS AND SLEEP IN ALZHEIMER'S DISEASE TRANSGENIC MODEL TGF344-AD

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Karel Blahna[1], Athira Nataraj[2], František Zitrický[2], Annu Kala[3], Susan Leemburg[2], Karel Jezek[3]

Hippocampus plays a pivotal role in spatial and episodic memory. Population activity of hippocampal place cells create neural representations of environments that are believed to represent network substrate of spatial memories. An important part of memory consolidation occurs during sleep via transient pattern reactivations when place cell firing patterns that occurred during active exploration are reactivated during sharp wave-ripple events. Disruption in these processes might significantly contribute to Alzheimer-related memory impairment. Here we explored changes in sleep-related memory processing in TgF344-AD transgenic rat model of Alzheimer disease (AD). This genetically modified model expresses two mutations implicated in AD: human amyloid precursor protein (APP) with Swedish mutation and human presenilin (PSEN) 1 with Δ exon 9 mutations. The impact of Alzheimer-like pathology on sleep-associated memory processing in TgF344-AD rats has not been described so far. In this study, we recorded hippocampal network activity in transgenic rats and age-matched mutation-free controls, while the animals explored familiar and novel environments and during preceding and following sleep epochs. We analyzed reactivation of place cell activity patterns during sleep, using methods based on cell-pairs co-activation and Bayesian decoding of sequential activity. In addition, we assessed changes in pyramidal cell and interneuronal population activity and neuronal synchrony across REM and non-REM sleep epochs. Our data show affected neural dynamics during sleep in AD model that might cause disturbed off-line memory processing during sleep in AD.

CHANGES IN HIPPOCAMPAL PLACE CELL CIRCUIT DYNAMICS IN 5XFAD MICE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Mary Ann Go, Seigfred Prado, Yimei Li, Simon Schultz
Imperial College London, Department Of Bioengineering, London, United Kingdom

The response of brain circuitry to amyloidosis is complex, with an interplay of cell-type-specific effects, changes in network dynamics, and altered network plasticity. Importantly, we need to understand how changes in circuit properties affect neuronal activity during memory encoding and recall. We recently (Go et al, Front Cellular Neurosci 2021) demonstrated the use of an air-lifted (non-VR) behavioural platform for mapping hippocampal place cell activity using two-photon imaging in head-fixed mice during spatial cognition. Here we present the first results from the application of this technology to the 5xFAD mouse model of Alzheimer's Disease (AD). We injected AAV-jGCaMP7s into the hippocampal CA1 region, then implanted an imaging window and metal headplate, aspirating the cortex above the injection site. Animals (6-9 months old) were trained for a week to run around a circular track, becoming familiarised to two environments. During imaging sessions, mice transitioned from a reference familiar environment to another familiar environment (evoking spatial memory recall) and to a novel environment (spatial memory encoding). Calcium fluorescence time series were tracked for hundreds of CA1 neurons over days. Our results show that 5xFAD mice are more active than wildtype mice in circular track navigation. Moreover, compared to place cells in wildtype littermate control mice, 5xFAD place cells have higher activity, wider place fields and less spatial information but they remap in a different environment to a similar degree. Further relating these properties to the plaque load for each imaged neuron may provide insight important for the development of effective AD therapeutics.

CA1 HYPEREXCITABILITY DRIVES ANESTHESIA-INDUCED EARLY MEMORY DYSFUNCTIONS IN ALZHEIMER'S MODEL MICE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Shiri Shoob[1], Nadav Buchbinder[1], Inna Slutsky[2]

Alzheimer disease (AD) is a progressive neurodegenerative disorder accounting for the majority of dementia cases. A presymptomatic phase of the disease precedes the onset of cognitive decline by decades. Recent epidemiological evidence suggests that postoperative cognitive dysfunction (POCD) is common after general anesthesia in the elderly. Moreover, clinical studies suggest a possible link between POCD and AD. In order to identify the network-wide mechanisms that drive GA-induced initial memory deficits, we used electrophysiology, chemogenetic perturbation of specific synaptic connections and behavior tasks. We found that anesthesia causes CA1 hyperexcitability and hypersynchrony in fAD, but not wild-type mice. This leads to a transient impairment in spatial working memory that correlates to the degree of CA1 hyperexcitability. Since thalamus deactivation is a common feature of general anesthesia, loss of inhibition in the thalamus might explain these state-dependent dysfunctions in fAD model. Indeed, thalamic nucleus reuniens (nRE) was hyperactive under anesthesia in fAD mice. Chemogenetic inactivation of the nucleus reuniens to CA1 synapse suppresses anesthesia-induced CA1 hyperexcitability. Further, deep brain stimulation of the nRE suppresses CA1 hyperexcitability and rescues spatial working memory impairments. These results point to CA1 hyperexcitability as a cause of memory deficits following general anesthesia and to the nucleus reuniens as a regulator of CA1 excitability and memory dysfunctions. Altogether, this study provides a novel circuit mechanism for POCD in AD patients.

DYSREGULATION OF CA1 HIPPOCAMPAL ACTIVITY ACROSS THE SLEEP-WAKE CYCLE IN ALZHEIMER'S DISEASE MOUSE MODEL

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Halit Baeloha[1], refaela Atsmon[2,3], Inna Slutsky[3,4]
[1]Tel Aviv university, Physiology And Pharmacology, יפו - תל אביב, Israel, [2]Tel Aviv University, Physiology And Pharmacology, Tel Aviv, Israel, [3]Tel Aviv University, Sagol School Of Neuroscience, Tel Aviv, Israel, [4]Tel Aviv University, Department Of Physiology And Pharmacology, Tel Aviv, Israel

Background Alzheimer's disease (AD) is a neurodegenerative disorder characterized by progressive memory decline. Accumulated evidence in AD patients and mouse models suggests that neuronal hyperexcitability in cortico-hippocampal circuits is part of the disease pathogenesis. Our recent results show that CA1 hyperexcitability can be revealed in AD mice model prior to the onset of cognitive symptoms by low-arousal brain states such as NREM sleep and anesthesia. These irregularities during sleep could be a contributing factor to the deteriorating cognitive function of AD patients since sleep plays a significant role in renormalizing synaptic strength and restoring cellular homeostasis. **Results** To characterize CA1 hyperexcitability during the pre-symptomatic stages of AD and its relation to the sleep-wake cycle, we studied 4-5-month-old APP/PS1 (APP_{SWE}/PS1DE9) mice that display a pathological increase in the Aβ42/Aβ40 ratio but do not exhibit impairments in hippocampus-dependent memory functions. EEG/LFP/EMG recordings, alongside video monitoring, were carried out continuously for several days on APP/PS1 mice and their WT littermates. No apparent changes in sleep architecture were detected during the light phase. During the dark phase, APP/PS1 mice spent less time in non-rapid eye movement (NREM) sleep and more time actively awake. **CA1 hyperexcitability, manifested mainly as interictal spikes, was present mainly during NREM and REM. Conclusions** Our results suggest that sleep is preserved during day, but disrupted during dark during presymptomatic AD stages. Understanding how circadian clock impairments affect this early sleep dysregulation and how it is connected to local dyshomeostasis of mean firing rates in the hippocampus during NREM sleep remains a challenge for the future studies.

E2F4DN-BASED GENE THERAPY RECOVERS LONG-TERM POTENTIATION AND HIPPOCAMPAL-DEPENDENT MEMORY IN HOMOZYGOUS 5XFAD MICE.

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Cristina Sánchez-Puelles[1,2], Gertrudis Perea[3], José Frade[1]
[1]Cajal Institute (CSIC), Molecular, Cellular And Developmental Neurobiology, Madrid, Spain, [2]Tetraneuron S.L., R+d Department, Valencia, Spain, [3]Cajal Institute (CSIC), Functional And Systems Neurobiology, Madrid, Spain

Neurons are usually regarded as postmitotic cells, nevertheless they can re-enter cell cycle and survive as hyperploid neurons during the course of different neurodegenerative diseases. Recently, it has been described that cell-cycle reentry, followed by DNA duplication (tetraploidization), and synaptic failure are two early hallmarks of Alzheimer's disease (AD). E2F4 becomes phosphorylated in APP/PS1 mice and in Alzheimer´s patients. We have demonstrated that the phosphorylation of two conserved Thr residues of E2F4 is necessary to induce neuronal tetraploidization and is related with cognitive loss in AD. Therefore, it was developed a therapy consisting in neuronal expression of a dominant negative form of E2F4 (E2F4DN), not phosphorylatable. This therapy has been patented and is licensed by Tetraneuron S.L., a Spanish spin-off biotech company. We hypothesized that viral expression of E2F4DN could correct AD-associated synaptic dysfunction. First of all, basal membrane properties were analyzed through whole-cell recordings in hippocampal primary cultures expressing E2F4DN. We demonstrated that it does not alter basal properties of hippocampal neurons. Afterwards, we expressed E2F4DN (AAV-E2F4DN intravenous administration) in control and homozygous 5xFAD mice. Synaptic function was measured by electrophysiological recordings of field excitatory postsynaptic potentials in hippocampal CA3-CA1 synapses. We found that E2F4DN recuperates long-term potentiation (LTP). Furthermore, this LTP recovery leads to cognitive improvement. 5xFAD mice treated with our therapy present a notably improvement in two hippocampal-dependent memory tasks (novel-object location and contextual fear conditioning). Thus, we report here that E2F4DN-based gene therapy represents a promising approach for AD treatment with capacity to prevent cognitive decline.

PTEN Activity Defines an Axis for Plasticity at Cortico-Amygdala Synapses and Influences Social Behavior.
Phosphatase and tensin homolog on chromosome 10 (PTEN) is a tumor suppressor and autism-associated gene that exerts an important influence over neuronal structure and function during development. In addition, it participates in synaptic plasticity processes in adulthood. As an attempt to assess synaptic and developmental mechanisms by which PTEN can modulate cognitive function, we studied the consequences of 2 different genetic manipulations in mice: presence of additional genomic copies of the Pten gene (Ptentg) and knock-in of a truncated Pten gene lacking its PDZ motif (Pten-ΔPDZ), which is required for interaction with synaptic proteins. Ptentg mice exhibit substantial microcephaly, structural hypoconnectivity, enhanced synaptic depression at cortico-amygdala synapses, reduced anxiety, and intensified social interactions. In contrast, Pten-ΔPDZ mice have a much more restricted phenotype, with normal synaptic connectivity, but impaired synaptic depression at cortico-amygdala synapses and virtually abolished social interactions. These results suggest that synaptic actions of PTEN in the amygdala contribute to specific behavioral traits, such as sociability. Also, PTEN appears to function as a bidirectional rheostat in the amygdala: reduction in PTEN activity at synapses is associated with less sociability, whereas enhanced PTEN activity accompanies hypersocial behavior.

GABAergic signaling to astrocytes in the prefrontal cortex sustains goal-directed behaviors.
GABA interneurons play a critical role in higher brain functions. Astrocytic glial cells interact with synapses throughout the whole brain and are recognized as regulatory elements of excitatory synaptic transmission. However, it is largely unknown how GABAergic interneurons and astrocytes interact and contribute to stable performance of complex behaviors. Here, we found that genetic ablation of GABA receptors in medial prefrontal cortex astrocytes altered low-gamma oscillations and firing properties of cortical neurons, which affected goal-directed behaviors. Remarkably, working memory deficits were restored by

optogenetic stimulation of astrocytes with melanopsin. Furthermore, melanopsin-activated astrocytes in wild-type mice enhanced the firing rate of cortical neurons and gamma oscillations, as well as improved cognition. Therefore, our work identifies astrocytes as a hub for controlling inhibition in cortical circuits, providing a novel pathway for the behaviorally relevant midrange time-scale regulation of cortical information processing and consistent goal-directed behaviors.

PTEN recruitment controls synaptic and cognitive function in Alzheimer's models.
Dyshomeostasis of amyloid-β peptide (Aβ) is responsible for synaptic malfunctions leading to cognitive deficits ranging from mild impairment to full-blown dementia in Alzheimer's disease. Aβ appears to skew synaptic plasticity events toward depression. We found that inhibition of PTEN, a lipid phosphatase that is essential to long-term depression, rescued normal synaptic function and cognition in cellular and animal models of Alzheimer's disease. Conversely, transgenic mice that overexpressed PTEN displayed synaptic depression that mimicked and occluded Aβ-induced depression. Mechanistically, Aβ triggers a PDZ-dependent recruitment of PTEN into the postsynaptic compartment. Using a PTEN knock-in mouse lacking the PDZ motif, and a cell-permeable interfering peptide, we found that this mechanism is crucial for Aβ-induced synaptic toxicity and cognitive dysfunction. Our results provide fundamental information on the molecular mechanisms of Aβ-induced synaptic malfunction and may offer new mechanism-based therapeutic targets to counteract downstream Aβ signaling.

Facilitation of AMPA receptor synaptic delivery as a molecular mechanism for cognitive enhancement.
Cell adhesion molecules and downstream growth factor-dependent signaling are critical for brain development and synaptic plasticity, and they have been linked to cognitive function in adult animals. We have previously developed a mimetic peptide (FGL) from the neural cell adhesion molecule (NCAM) that enhances spatial learning and memory in rats. We have now investigated the cellular and molecular basis of this cognitive enhancement, using biochemical, morphological, electrophysiological, and behavioral analyses. We have found that FGL triggers a long-lasting enhancement of synaptic transmission in hippocampal CA1 neurons. This effect is mediated by a facilitated synaptic delivery of AMPA receptors, which is accompanied by enhanced NMDA receptor-dependent long-term potentiation (LTP). Both LTP and cognitive enhancement are mediated by an initial PKC activation, which is followed by persistent CaMKII activation. These results provide a mechanistic link between facilitation of AMPA receptor synaptic delivery and improved hippocampal-dependent learning, induced by a pharmacological cognitive enhancer.

NEURONAL EXPRESSION OF E2F4DN MODULATES THE IMMUNE RESPONSE OBSERVED IN THE CEREBRAL CORTEX OF 5XFAD MICE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Morgan Ramón-Landreau[1], Noelia López-Sánchez[1], José Frade[2]
[1]Tetraneuron, S. L., R + D Department, Valencia, Spain, [2]Cajal Institute (CSIC), Molecular, Cellular And Developmental Neurobiology, Madrid, Spain

Alzheimer's disease (AD) is a neurodegenerative disorder in which altered immune response is an important etiological factor. The transcription factor E2F4 participates in tissue homeostasis and regulates gene networks affected in AD, thus constituting a potential target for intervention. We have studied whether neuronal expression of a dominant negative form of E2F4 (E2F4DN), can modulate the immune response observed in AD. To this aim, we generated Mapt:E2F4DN knock-in mice (E2F4DN mice) that, together with control Mapt:EGFP knock-in mice (EGFP mice), were crossed with 5xFAD mice, a known murine model of AD. Neuronal expression of E2F4DN in 5xFAD mice led to reduced astrogliosis at 3 months of age, both in cortex and hippocampus. In addition, Iba1-positive cells exhibited reduced size in the cortex and hippocampus of 5xFAD/E2F4DN mice at 3 and 6 months, suggesting that microglia activation is attenuated by the presence of neuronal E2F4DN. In vivo, most Iba1-positive cells of 5xFAD/E2F4DN mice were associated to amyloid beta (Aβ) deposits, which were increased in size, but not in number at 3 months of age. Moreover, neuronal expression of E2F4DN slowed down the accumulation of Aβ at 6 months of age. We speculate that the crosstalk between E2F4DN-expressing neurons and microglia favors the aggregation of oligomeric Aβ at early stages of AD, thus reducing its toxicity, and attenuates Aβ deposition at later stages. Altogether, our data are consistent with a beneficial immune response in 5xFAD mice expressing neuronal E2F4DN, which we propose as a therapeutic agent against AD.

AMYLOID BETA IMPAIRS SYNAPTIC PLASTICITY AT THE HIPPOCAMPAL CA3-CA1 SYNAPSES IN ALZHEIMER'S DISEASE: A COMPUTATIONAL MODELING STUDY

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Justinas Juozas Dainauskas[1], Michele Migliore[2], Hélène Marie[3], Aušra Saudargienė[1]
[1]Lithuanian University of Health Sciences, Neuroscience Institute, Kaunas, Lithuania, [2]National Research Council, Institute Of Biophysics, Palermo, Italy, [3]Institut de Pharmacologie Moléculaire et Cellulaire, Université Côte D'azur - Cnrs, Valbonne, France

Alzheimer's disease (AD) is a neurodegenerative disorder characterized by progressive memory loss, cognitive decline, language impairment, and decision making. It has a long preclinical stage, and before any clinical symptoms appear, pathological processes are observed in the hippocampus and entorhinal cortex, regions of the brain responsible for memory storage and recall. In early AD, alterations in amyloid precursor protein (APP) processing and clearance of APP peptides are observed. Increased APP levels lead to the production of AD-related peptides such as Amyloid beta (Aβ), Amyloid eta (Aη), and the Amyloid APP intracellular domain (AICD). In hippocampal CA1 pyramidal neurons, Aβ inhibits long-term potentiation (LTP) and enhances long-term depression (LTD) of glutamatergic synapses. The aim of this study is to investigate the mechanisms of the altered Aβ-induced synaptic plasticity applying a computational modeling approach. We used a detailed compartmental model of a CA1 pyramidal neuron and a modified NMDAr dependent voltage-based model of synaptic plasticity to analyze synaptic modifications at the hippocampal CA3-CA1 synapses. The effect of the elevated levels of Aβ was modeled as the increased extracellular glutamate concentration, endocytosis of synaptic AMPA receptors, reduced synaptic density, NMDA receptor-mediated activation of Ca2+/calmodulin-dependent kinase II (CaMKII). The modeling results support the experimental indication that pathological concentration of Aβ leads to impaired LTP and enhanced LTD in AD. Computational modeling study sheds light on the Aβ-induced complex processes and their interactions in shaping synaptic plasticity at the hippocampal synapses. Amyloid plaques made of β-peptides are one of the main hallmarks of the Alzheimer disease (AD). The study of the effects of longlasting space stays on the development of AD and other proteinopathies in astronauts is an urgent need in view of the programs for interplanetary travels announced by national and international space agencies. "Amyloid Aggregation" is an Italian Space Agency (ASI) project study aiming to assess how amyloid fibrils aggregation is affected by microgravity. The experiment was performed on the International Space Station (ISS) during the "BEYOND" mission. β-peptides of different size and propensity to aggregate were encapsulated in the cap of special jars containing the reaction fluid in separate lower compartment. Once on the ISS, β-peptides were mixed with the reaction fluid and left to aggregate at ambient temperature for various times. At the end of each interval, samples were frozen and then returned to Earth. The experiment was repeated on Earth recapitulating the same ISS conditions except for the absence of weight. Major techniques for amyloid characterization like Western Blotting, Mass Spectrometry, Atomic Force Microscopy, and Dynamic Light Scattering were optimized to compare the ISS samples with those processed on Earth. Preliminary results have shown differences between β-peptides aggregates formed aboard the ISS and on the Earth. Hopefully, results from this project will help to design more stringent scientific studies to evaluate the risk of developing protein aggregation diseases in astronauts.

MACHINE-LEARNING HISTOPATHOLOGICAL SEGMENTATION AND QUANTIFICATION OF TAUOPATHIES IN CLASSIC VS RAPIDLY PROGRESSIVE FORMS OF ALZHEIMER'S DISEASE.

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Lea Ingrassia[1], Daniel Racoceanu[2], Brainbank Neuroceb Neuropathology Network[3], Susana Boluda[3], Benoît Delatour[1], Lev Stimmer[1]
[1]Paris Brain Institute (ICM), Team Alzheimer's And Prion Diseases, Paris, France, [2]Paris Brain Institute (ICM), Aramis Inria Team, Paris, France, [3]Hôpital de la Pitié Salpêtrière, Escourolle Neuropathology Lab., Paris, France

Complex changes in the brain tissue including the accumulation of phosphorylated tau-positive somatic neurofibrillary tangles (NFT) and neuritic plaques (NP) characterize Alzheimer's disease. Recently discovered rapidly progressive AD (rpAD) present an atypically short clinical course, but
remains undistinguishable from classic AD (cAD) using current neuropathological analysis methods. In the present project, we aimed to automatically segment tau-positive objects (i.e. NP and NFT) and evaluate their load, morphology and spatial distribution in cAD and rpAD cases. We used whole slide images of AT8-immunostained sections of prefrontal cortices from eleven cAD and nine rpAD cases. Additional AD cases were included for algorithm training. A set of 15 slides was used for human-CNN iterative object annotation resulting in a total of 5013 annotated and expertvalidated NPs. A U-Net based CNN was trained and the obtained algorithm was precise in NP detection (F1 score: 0.84) and segmentation (F1 score: 0.75). NFTs detection-segmentation is currently work in progress using similar deep-learning approach. Using our algorithm applied to the cAD-rpAD cohort, NPs were segmented and their load and morphology were measured. cAD individuals presented a significantly higher NP load ($p<0,05$) in comparison to rpAD cases. Obtained segmentation data were crossed with available clinical and additional neuropathological data using PCA and t-SNE multivariate analysis leading to a clear differentiation of cAD and rpAD groups. Our data indicate the usefulness of deep learning-based histological analysis of tau lesions for
stratification of AD subgroups presenting apparent neuropathological isomorphism.

GENETICS OF ALZHEIMER-LIKE DISEASE IN OCTODON DEGUS

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Tania Rosas[1], Peter Mombaerts[1], Adrian Palacios[2]
[1]Max Planck Institute, Max Planck Research Unit For Neurogenetics, Frankfurt am Main, Germany, [2]University of Valparaiso, Cinv, Valparaiso, Chile

Various groups have reported the development of an Alzheimer-like disease in *Octodon degus* (DAD) held in captivity. The disease is characterized by the presence of typical human Alzheimer's brain biomarkers and a decline in cognitive performance. Interestingly, DAD has been observed in some degu laboratory colonies but not in others. Our aim is to find an explanation for the difference in DAD incidence among degu colonies, specifically to look for genetic variants that could be associated with the development of DAD. We performed behavioral assessments to detect cognitive decline, and sequenced the protein coding regions of 6 genes linked to Alzheimer's disease in human to look for sequence variants. The effect of these variants in protein stability was analyzed using 3D protein models. We studied degus with or without DAD from one colony in Chile and one in Germany. We discovered 15 non-synonymous variants in 4 genes: *APOE*, *PSEN2*, *MAPT*, and *TREM2*. Among these, 10 variants are predicted to affect protein stability, potentially producing deleterious effects in protein function. The variant in *APOE* also is predicted to change its affinity to HSPG receptors, which can lead to the emergence of DAD biomarkers. Variants are present in similar proportions between DAD and non-DAD individuals, but some are present in one colony but not in the other. We speculate that the higher frequency of certain variants in a colony confers higher propensity to DAD and that the synergistic effect of different variants could be a determinant for the development of DAD.

PROTEOMIC ANALYSIS ASSESSMENT OF HUMAN AMYGDALA IN ALZHEIMER'S DISEASE.

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Melania Gonzalez-Rodriguez, Veronica Astillero-Lopez, Sandra Villar-Conde, Villanueva-Anguita, Isabel Ubeda-Banon, Alicia Flores-Cuadrado, Daniel Saiz-Sanchez, Alino Martinez-Marcos
UNIV. CASTILLA-LA MANCHA, Facultad De Medicina De Ciudad Real, CIUDAD REAL, Spain

Alzheimer's disease (AD) is characterized by accumulation of extracellular amyloid-β and intracellular hyperphosphorylated tau. Due to early damage to the amygdala, personality changes often precede other clinical symptoms, such as cognitive impairment. Moreover, amygdala constitutes a key hub that may contribute to the spreading of pathologic molecules due to its vast connectivity with other brain regions. Therefore, amygdala constitutes an essential area for AD pathology that has been partially neglected. State-of-the-art -omic approaches would allow multilevel analysis but are currently underdeveloped. Proteomic studies on human tissue would be especially suitable to identify peptide fingerprint changes in human amygdala during pathology. Post-mortem tissue was provided by IDIBAPS, BTCIEN, BIOBANC-MUR, BPA and NAVARRABIOMED Spanish National Biobanks. A total of 16 cases were used for proteomic analyses consisted in PCA, heatmap, volcano plot and detection of activated/deactivated pathways. Immunofluorescence was performed for proteins distribution evaluation. Proteomic analysis revealed upregulated proteins related to pathological proteins formation (PPP1R1A and ANP32E) and cellular responses to pathology (SNRPA, DDX3X, GAN, RGCC, MACROH2A1, PSMB8). These results provided novel data on proteomic changes in human amygdala during AD and focus attention in potential biomarkers. The study was sponsored by the UCLM/ERDF (2021-GRIN-31233to NPND), Spanish Ministries of Economy and Competitiveness/ERDF (grant no. SAF2016-75768-R) and Science and Innovation (grant no. PID2019-108659RB-I00) to AMM and Autonomous Government of Castilla- La Mancha/ERDF (grant no. SBPLY/17/180501/000430) to AMM and DSS. MGR and SVC held a predoctoral fellowship granted by UCLM/ESF and VAL held an assistant professorship granted by UCLM/ERDF.

ANTI-GLUA3 ANTIBODIES IN FRONTOTEMPORAL DEMENTIA: AN IN VIVO APPROACH

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Maria Italia[1], Diego Scheggia[1], Elisa Zianni[1], Michela Salvadé[1], Filippo La Greca[1], Jennifer Stanic[1], Monica Di Luca[1], Barbara Borroni[2], Fabrizio Gardoni[1]

Background: Frontotemporal dementia (FTD) is a common type of presenile dementia that presents as a clinically and neuropathologically heterogeneous disorder. Recently, autoantibodies directed against the GluA3 subunit of AMPA-type glutamate receptors (AMPARs) have been identified in 20% to 25% of FTD patients. Data from patients and in vitro/ex vivo studies indicate that anti-GluA3 IgG negatively affect glutamatergic neurotransmission. *Aims:* We studied whether and how the chronic presence of anti-GluA3 IgG triggers a neurodegenerative process in mice and the association between this process and the appearance of FTD-related neuropathological and behavioural signature. What is more, we investigated a possible rescue strategy to counteract the detrimental effects mediated by anti-GluA3 IgG. *Methods:* We developed a chronic mouse model of autoimmunity in FTD by infusing mice with anti-GluA3 IgG isolated from FTD patients for one month through an intracerebroventricular cannula. The model was used to perform morphological and biochemical analyses and behavioural tasks. *Results:* Data showed that chronic anti-GluA3 IgG administration led to the appearance of FTD-related neuropathological markers and to dendritic spine loss in mice prefrontal cortex. In addition, we identified alterations in sociability and cognition that partially reflect those deficits proper of FTD GluA3+ patients. *Conclusions:* Our model allowed to identify the specific contribution of anti-GluA3 autoantibodies to FTD neuropathology which will be instrumental to the development of a putative therapeutic strategy for GluA3+ patients.

Rationale, Relevance, and Limits of Stress-Induced Psychopathology in Rodents as Models for Psychiatry Research: An Introductory Overview.
Emotional and cognitive information processing represent higher-order brain functions. They require coordinated interaction of specialized brain areas via a complex spatial and temporal equilibrium among neuronal cell-autonomous, circuitry, and network mechanisms. The delicate balance can be corrupted by stressful experiences, increasing the risk of developing psychopathologies in vulnerable individuals. Neuropsychiatric disorders affect twenty percent of the western world population, but therapies are still not effective for some patients. Elusive knowledge of molecular pathomechanisms and scarcity of objective biomarkers in humans present complex challenges, while the adoption of rodent models helps to improve our understanding of disease correlate and aids the search for novel pharmacological targets. Stress administration represents a strategy to induce, trace, and modify molecular and behavioral endophenotypes of mood disorders in animals. However, a mouse or rat model will only display one or a few endophenotypes of a specific human psychopathology, which cannot be in any case recapitulated as a whole. To override this issue, shared criteria have been adopted to deconstruct neuropsychiatric disorders, i.e., depression, into specific behavioral aspects, and inherent neurobiological substrates, also recognizable in lower mammals. In this work, we provide a rationale for rodent models of stress administration. In particular, comparing each rodent model with a real-life human traumatic experience, we intend to suggest an introductive guide to better comprehend and interpret these paradigms.

GluA3 autoantibodies induce alterations in dendritic spine and behavior in mice.
Autoantibodies targeting the GluA3 subunit of AMPA receptors (AMPARs) have been found in patients with Rasmussen's encephalitis and different types of epilepsy and were associated with the presence of learning and attention deficits. Our group recently identified the presence of anti-GluA3 immunoglobulin G (IgG) in about 25% of patients with frontotemporal dementia (FTD), thus suggesting a novel pathogenetic role also in chronic neurodegenerative diseases. However, the in vivo behavioral, molecular and morphological effects induced these antibodies are still unexplored. We injected anti-GluA3 IgG

purified from the serum of FTD patients, or control IgG, in mice by intracerebroventricular infusion. Biochemical analyses showed a reduction of synaptic levels of GluA3-containing AMPARs in the prefrontal cortex (PFC), and not in the hippocampus. Accordingly, animals injected with anti-GluA3 IgG showed significant changes in recognition memory and impairments in social behavior and in social cognitive functions. As visualized by confocal imaging, functional outcomes were paralleled by profound alterations of dendritic spine morphology in the PFC. All observed behavioral, molecular and morphological alterations were transient and not detected 10-14 days from anti-GluA3 IgG injection. Overall, our in vivo preclinical data provide novel insights into autoimmune encephalitis associated with anti-GluA3 IgG and indicate an additional pathological mechanism affecting the excitatory synapses in FTD patients carrying anti-GluA3 IgG that could contribute to clinical symptoms.

GluA3-containing AMPA receptors: From physiology to synaptic dysfunction in brain disorders.
In the mammalian brain, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-type glutamate receptors (AMPARs) play a fundamental role in the activation of excitatory synaptic transmission and the induction of different forms of synaptic plasticity. The modulation of the AMPAR tetramer subunit composition at synapses defines the functional properties of the receptor. During the last twenty years, several studies have evaluated the roles played by each subunit, from GluA1 to GluA4, in both physiological and pathological conditions. Here, we have focused our attention on GluA3-containing AMPARs, addressing their functional role in synaptic transmission and synaptic plasticity and their involvement in a variety of brain disorders. Although several aspects remain to be fully understood, GluA3 is a widely expressed and functionally relevant subunit in AMPARs involved in several brain circuits, and its pharmacological modulation could represent a novel approach for the rescue of altered glutamatergic synapses associated with neurodegenerative and neurodevelopmental disorders.

THE IMPACT OF ALZHEIMER'S DISEASE ON THE HUMAN SYNAPTOME

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Jessica Griffiths[1,2], Zhen Qiu[1], Theresa Wong[1], Beverley Notman[1], Johanna Jackson[2], Colin Smith[1], Seth Grant[1]
[1]University of Edinburgh, Centre For Clinical Brain Sciences, Edinburgh, United Kingdom, [2]Dementia Research Institute at Imperial College, Department Of Brain Sciences, London, United Kingdom

Introduction: Synapse pathology is one of the leading determinants of the onset and progression of Alzheimer's Disease (AD). With current therapies aimed at reducing and clearing pathogenic Aβ and tau failing, it is becoming increasingly apparent that we need to look at AD pathology differently, considering the impact of these toxic proteins on molecular diversity at the level of the synapse. **Aim:** As part of the UK Dementia Research Institute (DRI) multi- 'omics atlas project for AD (MAP-AD), we aimed to use synaptome mapping approaches to characterise synapse types and to identify vulnerable and resilient synapses throughout AD progression. **Methods**: By combining immunofluorescent labelling of synaptic proteins, high throughput single-synapse resolution spinning disk microscopy, and deep learning technology, we are developing a comprehensive synaptome mapping pipeline for human post-mortem tissue, assessing six cortical brain regions in early- (Braak III-IV) and late- (Braak V-VI) stage AD. **Results**: An optimised immunolabelling protocol has been established using data-driven approaches and a quantitative analysis of the results will be presented. Preliminary observations have shown spatiotemporal differences in both excitatory and inhibitory synaptic proteins and a systematic and quantitative analysis of the changes in AD will be assessed and presented. **Conclusion**: Uncovering the impact of synapse diversity on AD will provide invaluable information for identifying synapse-specific biomarkers and therapeutic strategies and to help resolve the fundamental mechanisms of cognitive decline in AD.

IMPAIRED DYNAMICS OF BRAIN PRECAPILLARY SPHINCTERS AND PERICYTES AT FIRST ORDER CAPILLARIES EXPLAINS REDUCED NEUROVASCULAR FUNCTIONS IN AGING

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Changsi Cai, Martin Lauritzen
University of Copenhagen, Department Of Neuroscience, Copenhagen, Denmark

The microvascular inflow tract (MIT), comprising the penetrating arterioles, precapillary sphincters, and first order capillaries, is the bottleneck for brain blood flow and energy supply. However, the exact structural and functional alterations of the MIT during aging remain elusive. *In vivo* 4-dimensional two-photon imaging showed an age-dependent decrease in vaso-responsivity, with reduced sensitivity of the MIT to pinacidil and papaverine, vasoconstrictor endothelin-1, and nitric oxide synthase inhibitor L-NAME. This was accompanied by an age-dependent decrease in capillary density close to the arterioles and loss of mural cell processes, though the number of mural cell somas and αSMA density were preserved. The age-related reduction in vascular reactivity was most pronounced at precapillary sphincters, highlighting their crucial role in capillary blood flow regulation. Mathematical modeling revealed dysregulated but preserved pressure and flow in aged mice during vasoconstriction. Preventing reduced responsivity of the MIT may ameliorate the blood flow decrease associated with aging-related brain frailty.

ANXIETY AND SOCIAL-LIKE DEFICITS IN ALZHEIMER'S DISEASE IN THE TGF344-AD RAT

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Daniela Cernotova, Anna Horakova, Kristyna Maleninska, Ales Stuchlik, Jan Svoboda
Institute of Physiology CAS, Laboratory Of Neurophysiology Of Memory, Prague, Czech Republic

Transgenic animal models in research of neuropsychiatric diseases consist primarily of mice. However, rats display a more complex behavioural repertoire, and their physiological and genetic background is more similar to humans. Therefore, studying Alzheimer's disease (AD) could benefit more from using rats rather than mice. We performed behavioural tasks assessing anxiety, spatial memory, and social interactions in 10- and 14-month-old TgF344-AD male and female rats and compared them to the control F344 rats. Our results showed that spatial acquisition and reversal in the Morris Water Maze task were surprisingly unaffected. In contrast, 10-month-old TgF344-AD male rats displayed an anxiety-like phenotype in the open field and elevated plus-maze. Interest in social interactions was significantly decreased in the TgF344-AD rats of both ages and sexes. We did not observe a worsening of the behavioural deficits with age. As the next step, we aim to analyse if the histopathological changes could have been reflected in performance. The project is supported by START/MED/099 grant and GACR grant GF21-16667K.

Transient Inactivation of the Medial Prefrontal Cortex and Ventral Hippocampus Impairs Active Place Avoidance Retrieval on a Rotating Arena.
It is well known that communication between the medial prefrontal cortex (mPFC) and the ventral hippocampus (vHPC) is critical for various cognitive and behavioral functions. However, the exact role of these structures in spatial coordination remains to be clarified. Here we sought to determine the involvement of the mPFC and the vHPC in the spatial retrieval of a previously learned active place avoidance task in adult male Long-Evans rats, using a combination of unilateral and bilateral local muscimol inactivations. Moreover, we tested the role of the vHPC-mPFC pathway by performing combined ipsilateral and contralateral inactivations. Our results showed not only bilateral inactivations of either structure, but also the combined inactivations impaired the retrieval of spatial memory, whereas unilateral one-structure inactivations did not yield any effect. Remarkably, muscimol injections in combined groups exerted similar deficits, regardless of whether the inactivations were contralateral or ipsilateral. These findings confirm the importance of these structures in spatial cognition and emphasize the importance of the intact functioning of the vHPC-mPFC pathway.
Front Neural Circuits, 2021; 15
34116140: Cernotova D, Stuchlik A, Svoboda J
Roles of the ventral hippocampus and medial prefrontal cortex in spatial reversal learning and attentional set-shifting.
Neural components enabling flexible cognition and behavior are well-established, and depend mostly on proper intercommunication within the prefrontal cortex (PFC) and striatum. However, dense projections from the ventral hippocampus (vHPC) alter the functioning of the medial PFC (mPFC). Dysfunctional hippocampo-prefrontal connectivity negatively affects the integrity of flexible cognition, especially in patients with schizophrenia. In this study, we aimed to test the role of the vHPC and mPFC in a place avoidance task on a rotating arena using two spatial flexibility task variants - reversal learning and set-shifting. To achieve this, we inactivated each of these structures in adult male Long-Evans rats by performing bilateral local muscimol (a GABA receptor agonist) injections. A significantly disrupted performance was observed in reversal learning in the vHPC-inactivated, but not in the mPFC-inactivated rats. These results confirm the notion that the vHPC participates in some forms of behavioral flexibility, especially when spatial cues are needed. It seems, rather unexpectedly, that the mPFC is not taxed in these flexibility tasks on a rotating arena.

EARLY DISRUPTION OF SOCIAL MEMORY IN A TGF344-AD RAT MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Karolína Hrůzová[1], Daniela Cernotova[2], Eduard Kelemen[3], David Levcik[1], Jan Svoboda[1], Ales Stuchlik[1]
[1]Institute of Physiology CAS, Laboratory Of Neurophysiology Of Memory, Prague, Czech Republic, [2]Institute of Physiology ASCR, Laboratory Of Neurophysiology Of Memory, Prague, Czech Republic, [3]National institute of mental health Czech Republic, Sleep And Chronobiology Research Centre, Klecany, Czech Republic

Social memory dysfunction is a frequent yet neglected hallmark of Alzheimer's disease (AD). The hippocampus, particularly CA2, is implicated in social memory. We used 6-month-old TgF344-AD rats, an animal model of AD, to investigate their social behaviour and memory and electrophysiological properties of their hippocampal CA2 region. We tested TgF344-AD male and female rats in a modified 5-trial social memory test (5-TSMT). This task consists of four trials presenting the first rat intruder in the subject's home cage, followed by the fifth trial presenting the second rat intruder. Compared to control F344 rats, TgF344-AD rats were less interested in the first intruders, indicating reduced sociability. Moreover, we found a diminished preference for social novelty in the TgF344-AD rats when the second intruder was presented. Next, we asked if AD is reflected in the electrophysiological properties of the CA2 in freely behaving TgF344-AD rats during the 5-TSMT and in the following memory consolidation during sleep. Analysis of electrophysiological LFP recordings from bilaterally implanted electrodes in CA2 is currently underway. We aim to analyze the power of theta and gamma frequency bands and sharp-wave ripples distribution during the consolidation period. **The project is supported by START/MED/099 grant and GACR grant GF21-16667K.**

THE C-TERMINAL OF MT5-MMP REGULATES C99 PROCESSING AND AMYLOID-BETA LEVELS IN A CELL MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Pedro Belio-Mairal, Laurence Louis, Angélique Jimenez, Delphine Stephan, Shweta Sonawane, Louise Greetham, Eric Di Pasquale, Emmanuel Nivet, Santiago Rivera
Aix-Marseille Université, Institut De Neurophysiopathologie, Cnrs, Inp, Marseille, France

Alzheimer's disease (AD) remains a major public health challenge without efficient treatment. Current knowledge of the molecular mechanisms involved in the amyloid hypothesis is insufficient to design effective therapeutic strategies. Recent advances have revealed a new therapeutic target upstream of amyloid beta (Aβ) production and accumulation - i.e., the APP β C-terminal fragment (C99) -, which correlates better with the symptomatology of the disease. In this context, we have identified the transmembrane/intracellular domains (TM/IC) of MT5-MMP (MT5 thereafter) as key regulators of C99 levels, with a direct impact on Aβ secretion, in mice and human-cell based models. Here, we used mutated variants of these MT5 domains to modulate C99 accumulation and Aβ secretion in human embryonic kidney cells (HEK) overexpressing C99. We found that the TM/IC of MT5 might be differently implicated in C99 trafficking and fate. Moreover, we identified two different groups of amino-acids at the N-terminal and C-terminal parts of the IC domain that are likely involved in the production and/or secretion of Aβ. Currently, we are transposing these experiments in a more physiological system based on neural cells derived from human induced pluripotent stem cells carrying AD-related mutations. In the near future we expect to: i) confirm the effects of our constructs on C99 metabolism in human neurons and ii) assess the outcome of this modulation on synaptic activity and integrity. Ultimately, our goal is to better understand the MT5 pathological mechanisms in AD in order to design therapeutic agents that can potentially counteract its effects.

AUDITORY SENSORY DEPRIVATION INDUCED BY NOISE EXPOSURE EXACERBATES COGNITIVE DECLINE AND HIPPOCAMPAL DYSFUNCTION IN A MOUSE MODEL OF ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Fabiola Paciello[1], Marco Rinaudo[1], Anna Pisani[2], Maria Vittoria Podda[1], Anna Rita Fetoni[3], Gaetano Paludetti[2], Claudio Grassi[1]
[1]Università Cattolica del Sacro Cuore, Department Of Neuroscience, Rome, Italy, [2]Università Cattolica del Sacro Cuore, Department Of Otolaryngology Head And Neck Surgery, Rome, Italy, [3]University of Naples Federico II, Unit Of Audiology, Department Of Neuroscience, Reproductive Sciences And Dentistry, Naples, Italy

Aims: Epidemiological evidence suggests a strong association between hearing loss and increased risk for the onset of neurodegenerative disorders, including Alzheimer's disease (AD). However, this relationship remains still controversial. The aim of this study was to evaluate in an animal model of AD (3×Tg-AD mice) if and how hearing loss induced by noise exposure at 2 months of age (when the AD phenotype is not manifest yet) can accelerate and/or worsen AD cognitive impairment, affecting auditory and hippocampal functions. **Methods:** 3×Tg-AD and B6129SF2/J wild-type mice of 2 months of age (M) were exposed to noise (pure tone, 10 kHz, 100 dB SPL, 10 days, 60 min/day). One and 4 months later (corresponding to 3 and 6 M), the detrimental effects of hearing loss in the auditory cortex and hippocampus were investigated by morphological (spine density analyses), electrophysiological (*ex-vivo* recordings of field-excitatory post-synaptic potentials -fEPSPs), behavioral, and molecular biology experiments (focusing on redox imbalance, neuroinflammation, and tau phosphorylation). **Results:** Noise-exposed 3×Tg-AD mice showed persistent synaptic and morphological alterations (reduced fEPSP amplitude and dendritic spine density) in the auditory cortex. Moreover, we found early hippocampal dysfunctions, such as decreased spine density in CA1 and dentate gyrus, decreased fEPSP amplitude, increased tau-phosphorylation, neuroinflammation, and oxidative stress, along with anticipated memory deficits compared to the expected neurodegenerative phenotype time-course. **Conclusion:** The mouse model of AD is more vulnerable to central nervous system damage induced by hearing loss and shows reduced ability to counteract noise-induced detrimental effects, which accelerates the neurodegenerative disease onset.

ASTROCYTIC CA2+ SIGNALING IN THE PROGRESSION OF ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Annamaria Lia[1], Angela Chiavegato[2], Miriana Sbrissa[2], Giorgio Carmignoto[1], Cristina Fasolato[2], Micaela Zonta[1]

Alzheimer's disease (AD) is a chronic incurable neurodegenerative disorder characterized by progressive memory loss and cognitive dysfunctions. Noteworthy, brain functions and dysfunctions are governed by dynamic interactions between neurons and astrocytes. We here evaluate the involvement of these glial cells in the pathogenesis of AD, focusing on astrocytic Ca^{2+} signaling and its dysregulation during AD progression. The experiments were carried out in female mice at 3 and 6 months of age, before and after, respectively, the onset of plaque deposition in the PS2APP mouse model of AD that expresses the human PS2-N141I and APP Swedish mutations. To investigate astrocytic activity, we performed two-photon Ca^{2+} imaging experiments in brain slice and *in vivo* preparations of somato-sensory cortex (SSCx) astrocytes expressing GCaMP6f. We found that astrocyte Ca^{2+} activity exhibits a sequence of changes: in 3-month-old PS2APP mice, spontaneous activity significantly increases, while in 6-month-old PS2APP mice both spontaneous activity and the responsiveness to agonists of different metabotropic receptors are drastically reduced in all astrocytic territories. Although these defects start in concomitance with plaque deposition, astrocytic Ca^{2+} hypoactivity is unrelated to plaque proximity. We evaluate the consequences of these alterations for SSCx long-term memory processes. Importantly, we found that in 6-month-old PS2APP mice astrocytic Ca^{2+} hypoactivity is associated to a strong impairment of long-term potentiation in SSCx circuits. In conclusion, astrocytic Ca^{2+} activity is strongly affected in AD at the onset of plaque deposition and can be considered as a functional hallmark of the disease.

Aims. Recent models of Alzheimer's Disease (AD) suggest the basal forebrain's nucleus basalis of Meynert (NbM) as the origin of structural degeneration followed by the entorhinal cortex (EC). Both brain regions show a selective vulnerability to proteinopathies and, thus, the spread of structural degeneration relates to harmonized CSF assays of amyloid-band hyperphosphorylated (pTau). Despite initial evidence from anatomical studies, the functional properties of NbM and EC during the disease progression of AD remain unclear. **Methods.** We analyzed open access data from the Alzheimer's Disease Neuroimaging Initiative (ADNI, n= 71) with CSF assays and resting-state fMRI data over two years. Specifically, fractional amplitude of low-frequency fluctuations (fALFF) was used to quantify spontaneous neuronal activity in BOLD fMRI (0.01-0.10 Hz) within the NbM and EC at baseline and two years later. Robust regression modeling was used to address the hypothesis of a spread from NbM to EC. **Results.** At baseline, fALFF differentiated between normal and abnormal CSF groups in both brain regions with a more pronounced reduction in NbM compared to EC. Importantly, only NbM activity at baseline predicted the annual percentage signal change in EC, but not the reverse. Accordingly, local activity within NbM but not EC linearly resembled the disease stage with highest activity in cognitive normal volunteers with normal CSF vs. lowest activity in AD patients with abnormal CSF. **Conclusions.** Our findings give novel insights into the pathogenesis of AD by showing that functional activity in the basal forebrain reliably predicts functional degeneration within the EC.

Alzheimer's disease (AD), a common form of dementia, is caused in part by the aggregation and accumulation in the brain of amyloid β (Aβ), a product of the proteolytic cleavage of amyloid precursor protein (APP) in endosomes. Trafficking of APP, such as surface-endosomal recycling, is an early critical step required for Aβ generation. Less is known, however, about the molecular mechanism regulating APP trafficking. In this study, we investigated the correlation of APP trafficking with SPIN90, along with Rab11, Aβ accumulation, and synaptic functionality. Brain Aβ accumulation was lower in the progeny of 5xFAD-SPIN90 KO than in 5xFAD-SPIN90 WT mice. Analysis of APP distribution and trafficking showed that the surface fraction of APP was locally distinct in axons and dendrites, with these distributions differing significantly in 5xFAD-SPIN90 WT and 5xFAD-SPIN90 KO mice, and neural activity-driven APP trafficking to the surface and endosomal recycling were more actively mobilized in 5xFAD-SPIN90 KO neurons. In addition, SPIN90 was found to be cotrafficked with APP via axons, with ablation of SPIN90 reducing the endosomal accumulation of APP in axons. Finally, synaptic transmission was restored over time in 5xFAD-SPIN90 KO, but not in 5xFAD-SPIN90 WT, neurons, suggesting SPIN90 is implicated in Aβ production by regulating APP trafficking.

CAN OLIGODENDROCYTES CONTRIBUTE TO Aβ PLAQUE FORMATION?

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Andrew Octavian Sasmita, Constanze Depp, Taisiia Nazarenko, Ting Sun, Lena Spieth, Klaus-Armin Nave
MPI for Multidisciplinary Sciences, City Campus, Neurogenetics, Göttingen, Germany

It is conventionally believed that amyloid plaques are aggregated products of amyloid beta (Aβ) solely produced by excitatory neurons. Within the central nervous system, however, key players of Aβ production, namely amyloid precursor protein and beta secretase (BACE), can be abundantly found in cells other than neurons as well, including oligodendrocytes. Here, we ask whether non-neuronal cells can contribute to the amyloid burden. We generated amyloidosis mice (APP NL-G-F) with cell-type-specific (i.e., excitatory neurons, NEX-Cre; oligodendrocytes, CNP-Cre) knock-out of BACE1 (Figure1A), the rate-limiting enzyme in Aβ production, to measure potential reductions in plaque formation. To this end, we employed light sheet microscopy to perform a whole brain 3D segmentation of amyloid plaques to bypass the spatial limitations of 2D imaging. First, we investigated whether plaques are still produced in mice lacking excitatory neuronal BACE1. At three and six months, these mice developed zero and very few plaques respectively in the forebrain (Figure1B), calling into question the critical Aβ concentration required for plaque deposition. Next, we assessed whether oligodendrocytes contribute to plaque burden. Surprisingly, we observed varying regional reductions in plaque formation in this model, with the largest attenuation seen in white matter tracts such as the alveus, where oligodendrocytes are ample (Figure1C). We concluded that: 1) Whole-brain plaque formation still requires the bulk of Aβ produced by forebrain excitatory neurons, and 2) To a lesser extent, oligodendrocytes do contribute to the amyloid burden, although it is less likely that they can initiate the advent of plaque

formation.

CENTRAL INCRETIN INHIBITION LEADS TO CHANGES IN BRAIN CELL ENERGY AND METABOLISM IN A RAT MODEL OF SPORADIC ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Aims The incretin system is an emerging new field that might provide valuable contributions to the research of pathophysiology and treatment of neurodegenerative disorders. We aimed to explore the role of central glucagon-like peptide-1 (GLP-1) and gastric inhibitory polypeptide (GIP) on cell metabolism and energy in the brain of a streptozotocin-induced rat model of sporadic Alzheimer's disease. Methods One month after streptozotocin-intracerebroventricular application (STZ-icv, 3 mg/kg), Wistar rats were icv treated with vehicle or respective antagonist of GLP-1 (Exendin (9-39) amide; (Ex9) or GIP-receptor (Pro-3GIP), and sacrificed 30 minutes afterward. Protein expression of: c-fos,p/tAMPK,COXIV,CytC in hippocampus (HPC) and hypothalamus (HPT) was measured by Western blot. Insulin,GLP-1 and GIP concentration in plasma was measured by ELISA, and glucose by GOD-PAP test. Data were analysed by Kruskal-Wallis one-way ANOVA and Mann-Whitney-U test ($p<0.05$). Results In HPC Ex9 and Pro-3GIP treatment decreased the ratio of p/tAMPK while in HPT decrement of COXIV of STZ-icv rats was found. Only Ex9 decreased c-fos both in control and STZ-icv rats in HPT, while in HPC increased c-fos was detected only in the STZ-icv group. CytC and glucose remained unchanged regardless the treatment. Pro-3GIP increased plasm insulin and GIP in STZ-icv rats and control while Ex9 decreased only plasma activ GLP-1 in STZ-icv rats. Conclusions Inhibition of the central GIP and GLP-1 receptor, respectively, in control and STZ-icv animals indicated a region-dependent role of incretins in the homeostasis of brain cell energy and metabolism and central incretin-dependent modulation of peripheral hormone secretion. *Funding:SCE-NEURO (*GA KK01.1.1.01.0007*), HRZZ-IP-2018-01-8938*

THE ROLE OF APOEε4 IN BRAIN LIPID METABOLISM IN DEMENTIA

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Qi Zhong[1], Brenan Durainayagam[1], Nirmal Verma[2], Paul Matthews[1], Paul Elliot[1], Florin Despa[2], Julian Griffin[1,3]

Apolipoprotein E (ApoE) is responsible for lipid transport between cells. *APOEε3* is the most common allele of the *APOE* gene among the population, while studies have shown a significantly increased risk of Alzheimer's disease (AD) in *APOEε4*-carriers compared to individuals with *ε3*. However, how *APOEε4* contributes to disease pathogenesis remains incompletely understood. Regarding the role of ApoE in lipid transport and the role of lipid metabolism in AD highlighted by previous -omic studies, the aim of our study is to investigate the difference in lipid profile between humanised *APOEε4* and *APOEε3* knock-in mice. We performed untargeted lipidomic profiling on brain tissue from 2-month and 6-month-old *APOEε4* and *APOEε3* mice by ultrahigh-performance liquid chromatography (UHPLC) ion-mobility mass spectrometry (IMMS). Results showed a decrease in phospholipids abundance including phosphatidylcholine in the 2-month *APOEε4* mice compared to *APOEε3* mice in the negative ionisation mode. In the 6-month mice group we also observed downregulation of phospholipids in *APOEε4* related to *APOEε3* in both ionisation modes. Additionally, sphingolipids, which have been implicated in AD, were significantly decreased in 2-month *APOEε4* mice in comparison to *APOEε3* mice. Our results suggest that *APOEε4* contributes to AD pathology via lipid metabolism modulation.

TOWARD THE ROLE OF SV2A PROTEIN IN HIPPOCAMPAL APP PROCESSING

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Ludmila Kasatkina, Vitaliy Gumenyuk, Olha Lisakovska, Irene Trikash
National Academy of Sciences of Ukraine, Research Laboratory For Young Scientists, Kyiv, Ukraine

In vivo brain imaging reveals that greater hippocampal activation at baseline is associated with increased Aβ accumulation and declining memory performance. Our previous data demonstrated that antiepileptic agent levetiracetam, a specific modulator of SV2A glycoprotein, is involved in the regulation of synaptic vesicle readiness for fusion and neurotransmitter release in hippocampus. As synaptic activity rapidly and dynamically affects Aβ levels, we aimed to study the action of $A\beta_{1-42}$ and $A\beta_{1-40}$ peptides on synaptic vesicle release, and the efficiency of levetiracetam therapy for complex inflammation-associated changes in hippocampus. Rats with LPS-induced neuroinflammation displayed the prevalence of excitatory over inhibitory transmission in hippocampus, impaired synaptic vesicle recycling and higher hippocampal APP levels, all being responsive to therapy with levetiracetam. We demonstrated that soluble oligomers of $A\beta_{1-40}$ and $A\beta_{1-42}$ peptides impair the storage capacity, clustering and Ca^{2+}-dependent fusion of SVs, which under intracellular accumulation of Aβ oligomers can reduce exocytotic neurotransmitter release. Oligomeric forms of $A\beta_{1-40}$ and $A\beta_{1-42}$ increase SV clustering and arrest the vesicles at this state, which significantly decreases their Ca^{2+}-triggered fusion. Therapy with levetiracetam upregulated hippocampal SV2A and restored the level of apolipoprotein E, involved in brain Aβ aggregation/clearance and resolution of inflammation. Our data suggests that in the course of progression of neuroinflammation oligomeric $A\beta_{1-42}$ and $A\beta_{1-40}$ can compromise synaptic vesicle fusion machinery and that levetiracetam, by acting on synaptic vesicle recycling and restricting overexcitation is able to affect APP processing and Aβ generation within the hippocampus *in vivo*.

Aims: Sporadic Alzheimer's disease (sAD) and metabolic dysfunction in type 2 diabetes mellitus share a common pathomechanism and drugs available for treatment of diabetes are increasingly being studied as possible sAD therapy. Hence, we aimed to research whether phloridzin, a non-selective sodium-glucose cotransporter inhibitor (SGLTI), may influence metabolic and cognitive parameters in a rat model of sAD. Methods: 4 groups (N=10) of 3-month-old Wistar rats were randomized to controls (CTR), sAD model induced by intracerebroventricular (icv) administration of streptozotocin (STZ; 3 mg/kg divided in two doses), CTR+SGLTI and STZ+SGLTI. SGLTI treatment by oral gavage (10 mg/kg) was initiated 1 month after STZ-icv and lasted two months. Cognitive assessment by Morris water maze and Passive avoidance tests was performed prior to sacrification and tissue collection. Results: SGLTI treatment failed to correct the cognitive deficit induced by STZ-icv in both tests. Weight gain in SGLTI treated rats was diminished compared to non-treated CTR and STZ-icv. While intraperitoneal glucose tolerance test revealed no differences between tested groups, plasma glucose levels were lowered by SGLTI in both CTR (-51%, p=0.0006) and STZ (-39%, p=0.0057) compared to CTR alone. Total glucagon-like peptide 1 (GLP-1) levels were altered both in plasma (-36% CTR+SGLTI vs CTR, p=0.0279; -28% STZ+SGLTI vs STZ, p=0.0535) and CSF (+59% STZ+SGLTI vs CTR, p=0.0115). Plasma and CSF glucose-dependent insulinotropic polypeptide (GIP) and CSF glucose levels were unchanged. Conclusions: Increased CSF GLP-1 levels opposing decreased peripheral ones indicates the brain's capacity to compensate for obstructed intestinal nutrient absorption. Funding: SCE-NEURO (GA KK01.1.1.01.000), HRZZ-IP-2018-01-8938.

INHIBITION OF BROMODOMAIN AND EXTRATERMINAL (BET) PROTEINS MODULATES THE EXPRESSION OF ALZHEIMER'S DISEASE RISK GENES IN MICROGLIA

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Mossakowski Medical Research Institute, Polish Academy of Sciences, Department Of Cellular Signalling, Warsaw, Poland

The genome-wide association studies proved the significant contribution of the immune system to the pathomechanism of Alzheimer's disease (AD). Data showed that polymorphism of several immune-related genes increases the risk of developing AD. Dysregulation of these genes' transcription may affect neuroinflammatory signaling and may potentially contribute to AD. A better understanding of mechanisms controlling the expression of these genes may enable novel therapeutical strategies for AD. In our study, we focused on bromodomain and extraterminal (BET) proteins, the readers of histone acetylation code, which have been demonstrated to control the expression of inflammation-related genes. We used a pharmacological (JQ1, 50 nM) approach for BETs' inhibition in mouse microglial BV2 cells, both in control conditions and in the presence of amyloid-beta (Aβ). The expression of tested genes was analyzed using the qPCR method. Our results demonstrated that JQ1 significantly reduced the expression of *Trem2* and *Cd33*, but increased mRNA levels for *Abca7*, *Bin1*, and *Cr1*. Transcription of *Cd2ap*, *Picalm*, and *Clu* was not changed by inhibition of BET proteins. The mRNA for *Epha1* was not detected in BV2 cells. Aβ had no significant impact on the transcription of tested genes in microglial cells. Our results demonstrated that BET proteins control mRNA levels of genes that were identified as genetic risk factors for AD, therefore the modulation of epigenetic regulation of transcription, including inhibition of BET proteins, may potentially offer a new strategy for controlling neuroinflammatory signaling in AD. TRAIL-R DEFICIENT MICE ARE PROTECTED FROM NEUROTOXIC EFFECTS OF AMYLOID-β

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Giulia Di Benedetto, Chiara Burgaletto, Maria Serapide, Antonio Munafò, Carlo Bellanca, Rosaria Di Mauro, Renato Bernardini, Giuseppina Cantarella
University of Catania, Department Of Biomedical And Biotechnological Sciences, Catania, Italy

TRAIL, a member of TNF superfamily, is a potent inducer of neuronal death. Neurotoxic effects of TRAIL appear mediated by its death receptor TRAIL-R2/DR5. To assess the role of TRAIL/TRAIL-R2 pathway in AD-related neurodegeneration, we studied the impact of the treatment with amyloid-β (Aβ) upon cell viability and inflammation in TRAIL-R-deficient mice (TRAIL-$R^{-/-}$). Here, we demonstrate that the lack of TRAIL-R2 protects from death cultured TRAIL-$R^{-/-}$ mouse embryonic hippocampal cells undergone treatment with either Aβ1-42 or TRAIL. Consistently, stereotaxic injection of Aβ1-42 resulted in blunted caspase activation, as well as in reduction of JNK phosphorylation and increased AKT phosphorylation in TRAIL-$R^{-/-}$ mice. Moreover, the lack of TRAIL-R2 was associated with blunted constitutive p53 expression in mice undergone Aβ1-42 treatment, as well as in decrease of phosphorylated forms of tau and GSK3β protein. Likewise, TRAIL-R2 appears essential to both TRAIL-Aβ mediated neurotoxicity and inflammation. Indeed, hippocampi of TRAIL-$R^{-/-}$ mice, challenged with Aβ1-42, showed a scanty expression of microglial (Iba-1) and astrocytic (GFAP) markers along with attenuated levels of IL-1β, TNF-a, iNOS and COX2. In conclusion, the bulk of these results demonstrate that the constitutive lack of TRAIL-R2 is associated with a substantial reduction of noxious effects of Aβ1-42, providing further evidence on the prominent role played by TRAIL in course of Aβ-related neurodegeneration and confirming that the TRAIL system represents a potential target for innovative AD therapy.

O-GLCNACYLATION ALLEVIATES THE PATHOLOGICAL FEATURES OF ALZHEIMER'S DISEASE BY INHIBITING NECROPTOSIS

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Yongeun Cho, Jinsu Park, Dong-Gyu Jo
Sungkyunkwan University, School Of Pharmacy, Suwon, Korea, Republic of

O-linked β-N-acetylglucosaminylation (O-GlcNAcylation) is a post translational modification which is enriched in brain and several O-GlcNAcylated proteins, such as tau and α-synuclein, are associated with neurodegenerative diseases. It has been known that O-linked β-N-acetylglucosaminase (OGA) inhibition decreased the amount of Aβ plaques in the brain of AD mouse models. Necroptosis has been found to be activated in humans' brains with AD and is positively correlated with the pathological features like neuronal death, neuroinflammation. Inhibition of necroptosis in AD effectively suppresses neuroinflammation. We evaluated the expression level of O-GlcNAcylation-related proteins, necroptosis-related proteins, and Aβ in human brain samples and mouse brain samples by western blotting and/or immunohistochemistry. Furthermore, we generated 5xFAD with OGA haploinsufficiency and evaluated the cognitive function by behavioral tests. Expression level of O-GlcNAcylation was decreased in both human brains with AD and 5xFAD brains. Also, the expression levels of necroptosis-related proteins were increased in both human brains with AD and 5xFAD brains. OGA haploinsufficiency increased O-GlcNAcylation levels in the brain and decreased activation of necroptosis, thereby reducing neuronal loss in the brain of 5xFAD. Furthermore, increased O-GlcNAcylation levels ameliorated cognitive deficits in 5xFAD mice and reduced Aβ accumulation. Here, we found that O-GlcNAcylation plays a protective role in AD by inhibiting necroptosis. O-GlcNAcylation ameliorated AD pathology including Aβ plaques, neuronal loss, neuroinflammation and cognitive decline. Thus, our data establish the influence of O-GlcNAcylation on Aβ accumulation and neurodegeneration, suggesting O-GlcNAcylation-based treatments as potential interventions for AD.

DELETERIOUS EFFECTS OF ALZHEIMER'S DISEASE-CAUSING PRESENILIN-1 MUTATIONS ON MITOCHONDRIAL DYNAMICS

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Sunyoung Park, Jihoon Han, Dong-Gyu Jo
Sungkyunkwan University, School Of Pharmacy, Suwon, Korea, Republic of

Mitochondrial dysfunction and oxidative stress are observed in Alzheimer's disease(AD). Studies have shown that presenilin-1(PS1) localizes to the mitochondrial membrane and regulates its homeostasis. Thus, we examined how five PS1 mutations(A431E, E280A, H163R, M146V, and Δexon9) observed in familial AD(FAD) affect mitochondria. We used H4 cell lines genetically engineered to express either the wild-type PS1 or one of the five PS1 mutants to examine mitochondrial homeostasis and functions. Furthermore, we used the brains of PS1M146V knock-in mice, 3xTg-AD mice, and human AD patients to investigate the role of PS1 in regulating MAMs formation. Each PS1 mutant exhibited slightly different mitochondrial dysfunction. Δexon9 mutant induced mitochondrial fragmentation while A431E, E280A, H163R, and M146V mutants increased MAMs formation. A431E, E280A, M146V, and Δexon9 mutants also induced mitochondrial ROS production. A431E mutant impaired both complexes I and peroxidase activity while M146V mutant only impaired peroxidase activity. All PS1 mutants compromised mitochondrial membrane potential and cellular ATP levels were reduced by A431E, M146V, and Δexon9 mutants. Comparative profiling of hippocampal gene expression in PS1M146V knock-in mice found that PS1M146V upregulates Atlastin 2(ATL2) expression level, which increases ER-mitochondria contacts. Moreover, ATL2 expression levels were significantly elevated in the brains of 3xTg-AD mice and AD patients. Overall, our findings suggest that each of the five FAD-linked PS1 mutations has a deleterious effect on mitochondrial functions. The adverse effects of PS1 mutations on mitochondria may contribute to MAMs formation and oxidative stress resulting in an accelerated age of disease onset in people harboring mutant PS1.

NRF2 REGULATES BACE1 AND BACE1-AS EXPRESSION IN A NEGATIVE WAY

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Hyejin Ju, Jeein Lim, Gahee Bahn, Dong-Gyu Jo
Sungkyunkwan University, School Of Pharmacy, Suwon, Korea, Republic of

BACE1 is the rate-limiting enzyme for amyloid-β peptides (Aβ) generation, mainly involved in the pathogenesis of Alzheimer's disease (AD). Through an undiscovered mechanism, levels of BACE1 and a BACE1 mRNA-stabilizing antisense RNA (BACE1-AS) are increased in the brains of AD patients; implicating that dysregulation of BACE1 expression can have an effect on the AD pathogenesis. We found that nuclear factor erythroid-derived 2-related factor 2 (NRF2/NFE2L2) represses the expression of BACE1 and BACE1-AS through binding to antioxidant response elements (AREs) in their promoters of mouse and human. NRF2-mediated inhibition of BACE1 and BACE1-AS expression is independent of redox regulation. NRF2 activation decreases production of BACE1 and BACE1-AS transcripts and Aβ production, and ameliorates cognitive deficits in animal models of AD. Depletion of NRF2 increases BACE1 and BACE1-AS expression and Aβ production, and worsens cognitive deficits. Our findings suggest that activation of NRF2 can prevent a crucial early pathogenic process in AD pathogenesis.

PREVENTION OF AMYLOIDOGENESIS BY NEURONAL AQUAPORIN 1 INHIBITING THE INTERACTION BETWEEN AMYLOID PRECURSOR PROTEIN AND BACE 1 IN ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Heejin Yoo, Jeonghyeong Im, Yoonsuk Cho, Jinsu Park, Dong-Gyu Jo
Sungkyunkwan University, Pharmacy, Jangan-gu, Suwon-si, Gyeonggi-do, Korea, Republic of

Aquaporin1 (AQP1) which belongs to the AQP family, is a membrane water channel protein. In the previous studies, it has been shown that levels of AQP1 was increased in the brain of Alzheimer's disease (AD), while the precise role of AQP1 in AD pathogenesis is unclear. In this study, we determined the expression and distribution of AQP1 in the brains of individuals with AD as well as AD mouse models. In AD patients, AQP1 was accumulated in vulnerable neurons in the cerebral cortex, and in AD mouse models, the expression of AQP1 increased with aging. We identified increased expression of AQP1 and translocation to endocytic compartments in response to stress stimuli. Considering the interaction of amyloid precursor protein (APP) with β-secretase (BACE1) in the endocytic compartments, AQP1 could inhibit the BACE1 mediated amyloidogenic APP processing which produces the neurotoxic amyloid beta (Aβ), a hallmark of AD. Consistently, a public human brain database demonstrated the negative correlation between AQP1 and Aβ levels. Collectively, these results indicate that upregulation of AQP1 expression in the brains of AD patients may be an adaptive response to cellular stress to prevent Aβ generation by suppressing the interaction between APP and BACE1.

REGION-SPECIFIC ALTERATIONS OF ASTROCYTIC K+ CLEARANCE IN A MOUSE MODEL FOR ALZHEIMER'S DISEASE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Evgeniia Samokhina, Yossi Buskila
Western Sydney University, School Of Medicine, Campbelltown, Australia

Aims: Alzheimer's disease (AD) is an age-dependent neurodegenerative disorder characterised by neuronal loss and neuronal hyperexcitability which emerges during the initial stages of the disease. Previous studies indicated that astrocytes, which are responsible for K^+ homeostasis in the CNS, can affect the excitability profile of neurons via alterations in their K^+ clearance properties. Hence, the aim of this study is to assess the astrocytic K^+ clearance rate in the hippocampus and somatosensory cortex in a mouse model of AD during disease progression. Methods: Simultaneous extracellular recordings of the K^+ clearance rate and astrocytic inward currents in acute brain slices containing the somatosensory cortex and hippocampus. All recordings were taken from a mouse model for AD (5xFAD) and their littermate controls at presymptomatic and symptomatic stages (two and six months respectively). Results: We found that following transient local application of a high concentration of K^+, the K^+ clearance rate in the hippocampus of 5xFAD mice was significantly lower at both presymptomatic and symptomatic stages. This decrease was accompanied by a decrease in astrocytic inward currents in the hippocampus, but not the somatosensory cortex of 5xFAD mice. Moreover, selective inhibition of Kir4.1 channels and Cx-43 channels indicated significant differences between the clearance mechanisms at the hippocampus and the somatosensory cortices of 5xFAD mice. Conclusions: Our results indicate a region-specific dysfunction of astrocytes in 5xFAD mice expressed as a reduced K^+ clearance rate in the hippocampus but not in the somatosensory cortex. The mechanisms leading to this dysfunction involve astrocytic channels: Kir4.1 and Cx-43.

IN VIVO LONGITUDINAL IMAGING OF RESTING STATE CONNECTIVITY IN HUMANIZED APP KI1 AND KI3 MICE

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Esmin Unaran[1], Taylor Schmitz[1], Amr Eed[1], Geoff Ngo[2], Marco Antônio Prado[3], Vânia Prado[3], Ravi Menon[1]
[1]Western University, Neuroscience, London, Canada, [2]Western University, Medical Biophysics, London, Canada, [3]Western Ontario University, Physiology And Pharmacology/department Of Anatomy & Cell Biology, Ontario, Canada

Alzheimer Disease (AD) is a progressive neurodegenerative disorder and the most common form of dementia that primarily effects elderly people, causing atrophy and loss of brain cells which results in a decline in memory, thinking, behavioral and social skills. The *amyloid cascade hypothesis* of AD proposes that extracellular accumulation of amyloid beta (Aβ) peptide triggers aggregation of hyperphosphorylated tau as intracellular neurofibrillary tangles which ultimately spreads across anatomically and functionally connected brain networks, yielding widespread neurodegeneration and impairment in brain function (Ricciarelli et al., 2017). For patients at this stage of the disease, it is too late: available treatments have little efficacy. It is critical, therefore, to develop treatments for intervention early in the disease, before widespread cell death renders intervention futile. First, we need to understand the early changes occurring in the AD brain, to identify targets, biomarkers, and models that can be used to develop effective early therapies. To achieve this aim, we have combined two strategies, second-generation mouse models and resting-state functional magnetic resonance imaging (rs-fMRI). We used second-generation AD mouse model carrying 3 mutations; Iberian, Artic, and Swedish ($APP^{NL\text{-}G\text{-}F/NL\text{-}G\text{-}F}$ or 'APP-KI-3' mouse) and $APP^{NL/NL}$ controls. All animals scanned using 9.4T Bruker preclinical MRI for small animals and anesthetized during scanning procedures. To compare the rs-networks before and after the progression of Aβ accumulation, we scanned the same animals at 3 months and 7 months of age. Our preliminary results indicates that there was a decrease in functional connectivity at 7 months of age with APP-KI-3 mouse.

INCREASED INCIDENCE OF DEMENTIA FOLLOWING HERPESVIRUS INFECTION IN THE KOREAN POPULATION

POSTER SESSION 07 - SECTION: ALZHEIMER'S DISEASE

Yongsoo Shim
The Catholic University of Korea, Neurology, Seoul, Korea, Republic of

Background: Herpesviruses affect the development of dementia. We investigated the association between herpes infection and subsequent diagnoses of dementia. Methods: Data from the National Health Insurance Service of South Korea were used. Patients aged ≥ 50 years with the relevant diagnostic codes in the reference year 2009 were included and prospectively reviewed from January 2010 to December 2018. All study participants were followed from the index date until the onset of dementia, death, or the study endpoint. Results: The three cohorts comprised 92,095 patients with herpes simplex virus (HSV) infections, 97,323 patients with varicella-zoster virus (VZV) infections, and 183,779 controls. During the follow-up period, 15,831 (17.19%) subjects with HSV infection and 17,082 (17.55%) VZVinfected subjects, compared to 27,028 (14.17%) control subjects, were subsequently diagnosed with dementia (all, P<0.001). The adjusted hazard ratio for developing dementia was found to be 1.18 (95% confidence interval [CI]; 1.16-1.20) in HSV and 1.09 (95% CI; 1.07-1.11) in VZV patients (all, P<0.001). HSV1 infections such as oral or ocular subtypes, but not HSV2, anogenital subtype, were associated with dementia, including several subtypes such as Alzheimer's disease (AD), vascular dementia, and dementia with Lewy bodies. VZV infection is also associated with AD. Conclusion: In this Korean nationwide population-based cohort study, both HSV and VZV infections were associated with a higher risk of dementia, particularly AD. Among the subtypes of HSV infection, HSV1 is associated with a risk of dementia. Further studies including appropriate public health interventions could evaluate the causality of these relationships.

MOLECULAR MECHANISM AND EXPERIMENTAL THERAPEUTICS OF ADCY5-RELATED MOVEMENT DISORDER: STUDY OF A NEW GENETIC MOUSE MODEL AND IDENTIFICATION OF THERAPEUTIC TARGETS.

POSTER SESSION 07 - SECTION: NEURODEGENERATIVE DISEASES

Ruiyi Yuan[1,2,3], Louise-Laure Mariani[2,3,4], Emmanuel Flamand-Roze[2,3,4]
[1]Institut du Fer à Moulin, Neurotransmission And Signalisation, Paris, France, [2]Institut du Cerveau, Mouvement Disorders, Paris, France, [3]Sorbonne Université, Neurosciences, Paris, France, [4]Hôpitaux Universitaires Pitié Salpêtrière, Mouvement Disorders, Paris, France

ADCY5-related movement disorder (*ADCY5*-MDS) is a neurological disorder characterized by childhood-onset generalized hyperkinetic movements due to dominant mutations of *ADCY5*. The *ADCY5* gene encodes the adenylyl cyclase 5 (AC5), which plays a key role in cyclic AMP (cAMP) synthesis within the striatum downstream of adenosine and dopamine receptors. AC5 participates in the control of movements by modulating the subtle balance between the activity of the direct striatal-nigral and indirect striatal-pallidal pathways. To investigate the pathogenesis of this disorder and identify therapeutic targets, we generated a genetic mouse model of *ADCY5*-MDS harboring the R418W mutation, which is frequently responsible for *ADCY5*-MDS. In this model, we want to (1) describe the molecular consequences of the *ADCY5* mutation (2) characterize the motor and behavioral phenotypes, (3) test in the effects of various pharmacological modulation aimed at altering striatal cAMP concentration. Our current results indicate an increased activity of the mutant AC5 with a compensatory down-regulation of the expression of AC5 and its upstream partners in the signaling cascade together with an increased phosphorylation of the downstream targets. Mutant mice have an abnormal locomotor activity, an impaired motor coordination, a defective motor learning and an anxiety-like behavior, consistent with the human phenotypes. We observed a differential molecular and motor response of the mutant mice to the administration of an $A2_A$ receptor antagonist. We are now planning to achieve a full molecular, motor and behavioral characterization of the model and to test in details the reversibility of the observed abnormalities in response to pharmacological intervention.

COORDINATION OF BET FAMILY PROTEINS IN FRAGILE X SYNDROME

POSTER SESSION 07 - SECTION: NEURODEGENERATIVE DISEASES

Tae-Kyung Kim
POSTECH, Life Sciences, Bio Open Innovation Center (boic), Pohang, Gyeongbuk, Korea, Republic of

Bromodomain and extraterminal proteins (BET) are epigenetic readers that play critical roles in gene regulation. Pharmacologic inhibition of the bromodomain present in all BET family members is a promising therapeutic strategy for various diseases, but its impact on individual family members has not been well understood. Using a transcriptional induction paradigm in neurons, we have systematically demonstrated that three major BET family proteins (BRD2/3/4) participated in transcription with different recruitment kinetics, interdependency, and sensitivity to a bromodomain inhibitor, JQ1. In a mouse model of fragile X syndrome (FXS), BRD2/3 and BRD4 showed oppositely altered expression and chromatin binding, correlating with transcriptional dysregulation. Acute inhibition of CBP/p300 histone acetyltransferase (HAT) activity restored the altered binding patterns of BRD2 and BRD4 and rescued memory impairment in FXS. Our study emphasizes the importance of understanding the BET coordination controlled by a balanced action between HATs with different substrate specificity.

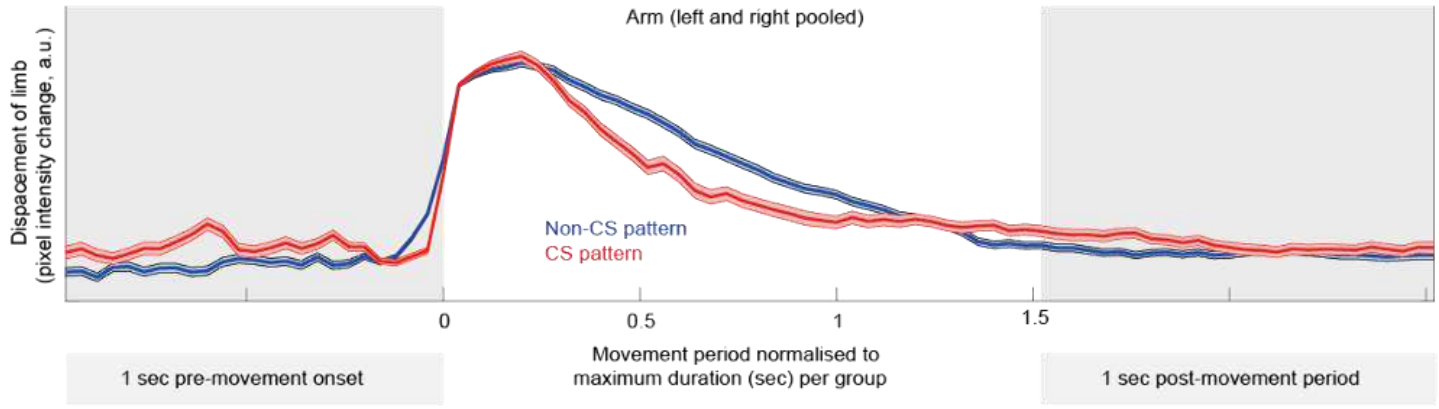
QUANTIFICATION OF NEONATAL MOTOR ACTIVITY AFTER BRAIN INJURY

POSTER SESSION 07 - SECTION: NEURODEGENERATIVE DISEASES

Neelum Mistry[1], James Dooley[2], Sarah Hines[3], Judith Meek[3], Mark Blumberg[2], Kimberley Whitehead[1]
[1]University College London, Neuroscience, Physiology And Pharmacology, London, United Kingdom, [2]University of Iowa, Department Of Psychological & Brain Sciences, Iowa City, United States of America, [3]University College London Hospitals, Elizabeth Garrett Anderson Obstetric Wing, London, United Kingdom

Aims In awake human neonates, spontaneous motor activity typically comprises fluid multi-limb sequences that join together individual movements lasting for ~1 sec. Absence of fluidity - the 'cramped-synchronised' (CS) pattern - has 97-100% specificity for later cerebral palsy. Here we quantified the individual limb movements underlying these two motor patterns. **Methods** Subjects were 23 neonates at risk for having sustained a brain injury. Motor activity at full-term was qualitatively scored as CS or non-CS using the Prechtl method. To quantify individual movements from video recordings, we detected frame-by-frame changes in pixel intensity within regions-of-interest. Movements were defined as ending 0.5 sec after pixel intensity change decreased below threshold, up to a maximum duration of 1.5 sec. **Results** Motor activity was scored as CS in 7/23 and non-CS in 16/23 neonates. 964 CS and 2282 non-CS movements were analysed. CS arm (but not leg) movements exhibited a significantly sharper trajectory offset (Figure) and were shorter than non-CS movements (median duration: 0.64 vs. 0.68 sec, p <.001, Mann-Whitney U
test).



Conclusions Abnormal motor function can be detected at full-term. There is a potential therapeutic window during the neonatal period to strengthen motor cortical networks. Given that recovery from injury is cortical activity-dependent in age-equivalent rats and mice, future work will examine the feasibility of modulating cortical activity to improve motor outcomes.

Each year, prematurity represents more than one out of ten births worldwilde. In premature newborns, complications may occur, such as an hypoxic-ischemic (HI) event which can lead to cerebral palsy (CP) in extreme cases. CP is defined as permanent disorders of movements and posture. Boys display a greater vulnerability to develop CP than girls do. Magnesium sulfate ($MgSO_4$) is administered to mothers at risk of preterm delivery as a neuroprotective agent. However, its effectiveness is only partial. To improve its effect, a new project has been developed in the lab, consisting in combining $MgSO_4$ with a second molecule presenting neuroprotective properties. 4-phenylbutyrate (4-PBA) was selected because it presents these characteristics and it is already administered in newborns. By using a mouse model of neonatal HI, generating lesions similar to those reported in preterms, we compared $MgSO_4$ effects with the effects of the $MgSO_4$/4-PBA association, on HI-induced alterations. Effects were evaluated at behavioral and histological levels, from the postnatal period until adolescence, while investigating sex effects. In non-HI individuals, treatments potential deleterious effects were sought. At short term, both $MgSO_4$ alone and the $MgSO_4$/4-PBA association prevent HI-induced histological and behavioral alterations. At long term, the $MgSO_4$ alone tends to prevent some HI-induced behavioral impairments whereas the $MgSO_4$/4-PBA association significantly prevents HI-induced motor and cognitive alterations. Neither treatments present proper effects at short or long terms. It will then be necessary to decipher treatments molecular mechanisms underlying neuroprotection, focusing on a potential prevention of HI-induced white matter injuries and oligodendrocyte differentiation alteration.

MUTATED KIDINS220 ACCUMULATES IN CELLS AND DISRUPTS HOMEOSTASIS – A POSSIBLE MECHANISM BEHIND SINO SYNDROME.

POSTER SESSION 07 - SECTION: NEURODEGENERATIVE DISEASES

Alicja Krawczun-Rygmaczewska[1,2], Martina Albini[2,3], Fabio Benfenati[2,4], Fabrizia Cesca[1,2]
[1]University of Trieste, Department Of Life Sciences, Trieste, Italy, [2]Fondazione Istituto Italiano di Tecnologia, Center For Synaptic Neuroscience And Technology, Genova, Italy, [3]University of Genova, Department Of Experimental Medicine, Genova, Italy, [4]IRCCS, Ospedale Policlinico San Martino, Genova, Italy

Introduction: SINO is a newly described syndrome characterized by Spastic paraplegia, Intellectual Disability, Nystagmus and Obesity, caused by heterozygous mutations in the KIDINS220 gene. Kidins220 (kinase D interacting substrate of 220kDa) is a multi-functional scaffold protein abundantly expressed across the nervous system. Some KIDINS220 pathogenic mutations result in shortened proteins resembling the isoforms naturally expressed during adulthood. **Aims**: This work examines the molecular consequences of KIDINS220 mutations. The main goals are to assess the effect the mutations on protein expression and how altered Kidins220 impacts cell homeostasis. **Methods**: Chosen mutations were introduced into the WT human KIDINS220 gene and expressed in HEK293T cells. We used western blotting and immunocytochemistry experiments to investigate Kidins220 protein expression levels, its cellular localisation and expression of cell homeostasis and autophagy molecular factors. **Results:** All but one of the KIDINS220 mutations investigated in this study were expressed in HEK293T cells. Mutated proteins were overexpressed in the target cells and formed aggregates in a pattern that varied between different mutations. We saw changes in levels of p62 receptor and LC3 protein in cells with mutated proteins. **Conclusions:** Different KIDINS220 mutations have a distinct effect on the translated protein, resulting in formation of protein aggregates in the affected cells. Variability in the mutation consequences depended on the mutation location in the gene. Our results indicate that mutated proteins impact the homeostasis of the affected cells possibly leading to the formation of autophagosomes. Further studies on the energetic profiles and mitochondrial functioning of the affected cells are ongoing.

Kidins220/ARMS modulates brain morphology and anxiety-like traits in adult mice.
Kinase D interacting substrate of 220 kDa (Kidins220), also known as ankyrin repeat-rich membrane spanning (ARMS), is a transmembrane scaffold protein that participates in fundamental aspects of neuronal physiology including cell survival, differentiation, and synaptic plasticity. The Kidins220 constitutive knockout line displays developmental defects in the nervous and cardiovascular systems that lead to embryonic lethality, which has so far precluded the study of this protein in the adult. Moreover, Kidins220 mRNA is tightly regulated by alternative splicing, whose impact on nervous system physiology has not yet been addressed in vivo. Here, we have asked to what extent the absence of Kidins220 splicing and the selective knockout of Kidins220 impact on adult brain homeostasis. To answer this question, we used a floxed line that expresses only the full-length, non-spliced Kidins220 mRNA, and a forebrain-specific, CaMKII-Cre driven Kidins220 conditional knockout (cKO) line. Kidins220 cKO brains are characterized by enlarged ventricles in the absence of cell death, and by deficient dendritic arborization in several cortical regions. The deletion of Kidins220 leads to behavioral changes, such as reduced anxiety-like traits linked to alterations in TrkB-BDNF signaling and sex-dependent alterations of hippocampal-dependent spatial memory. Kidins220 floxed mice present similarly enlarged brain ventricles and increased associative memory. Thus, both the absolute levels of Kidins220 expression and its splicing pattern are required for the correct brain development and related expression of behavioral phenotypes. These findings are relevant in light of the increasing evidence linking mutations in the human KIDINS220 gene to the onset of severe neurodevelopmental disorders.

Intranasal oxytocin increases heart-rate variability in men at clinical high risk for psychosis: a proof-of-concept study.
Autonomic nervous system (ANS) dysfunction (i.e., increased sympathetic and/or decreased parasympathetic activity) has been proposed to contribute to psychosis vulnerability. Yet, we still lack directed therapeutic strategies that improve ANS

regulation in psychosis or at-risk states. The oxytocin system constitutes a potential therapeutic target, given its role in ANS regulation. However, whether intranasal oxytocin ameliorates autonomic regulation during emerging psychosis is currently unknown. We pooled together two datasets, one of 30 men at clinical high risk for psychosis (CHR-P), and another of 17 healthy men, who had participated in two double-blinded, placebo-controlled, randomised, crossover MRI studies with similar protocols. All participants self-administered 40 IU of intranasal oxytocin or placebo using a nasal spray. We recorded pulse plethysmography during a period of 8 min at about 1 h post dosing and estimated heart rate (HR) and high-frequency HR variability (HF-HRV), an index of cardio-parasympathetic activity. CHR-P and healthy men did not differ at resting HR or HF-HRV under placebo. We found a significant condition × treatment effect for HF-HRV, showing that intranasal oxytocin, compared with placebo, increased HF-HRV in CHR-P but not in healthy men. The main effects of treatment and condition were not significant. In this proof-of-concept study, we show that intranasal oxytocin increases cardio-parasympathetic activity in CHR-P men, highlighting its therapeutic potential to improve autonomic regulation in this clinical group. Our findings support the need for further research on the preventive and therapeutic potential of intranasal oxytocin during emerging psychosis, where we lack effective treatments.

Dystonia is the third most common movement disorder, characterized by involuntary and sustained muscle contractions. DYT25, an adult-onset isolated form of dystonia, is caused by loss-of-function mutations in the GNAL gene. GNAL encodes the olfactory type G-protein alpha subunit, highly enriched in the corpus striatum of the basal ganglia network. Notably, the involvement of the striatum in dystonia pathophysiology is well known. In the present work, we investigated the striatal molecular and electrophysiological alterations in a newly generated heterozygous GNAL knockout rat model. GNAL+/- rats exhibited an altered behavioural phenotype, showing decreased locomotor activity and impaired motor coordination. We found an impairment of striatal synaptic plasticity in GNAL+/- rats, with loss of dopamine-dependent Long-Term Synaptic Depression (LTD). Further electrophysiology experiments showed that striatal LTD was partially rescued by a combination of both dopamine D1R and D2 receptor (D2R) agonists. Additionally, LTD was fully rescued by antagonism of either adenosine A2AR or type 5 metabotropic glutamate receptor (mGlu5R). Notably, both A2AR and mGlu5R exert antagonistic actions on striatal D2R. Therefore, the full rescue of LTD was likely obtained by relieving the inhibitory action of these receptors on D2R. Ongoing electrophysiology and immunoblotting experiments are characterizing the molecular mechanisms of both LTD impairment and its pharmacological rescue by A2AR and mGlu5R antagonists. These data will provide important insights on the pathophysiology of the debilitating and incurable DYT25 dystonia, and on new pharmacological targets for novel and more effective therapies.

Models of dystonia: an update.
Although dystonia represents the third most common movement disorder, its pathophysiology remains still poorly understood. In the past two decades, multiple models have been generated, improving our knowledge on the molecular and cellular bases of this heterogeneous group of movement disorders. In this short survey, we will focus on recently generated novel models of DYT1 dystonia, the most common form of genetic, "isolated" dystonia. These models clearly indicate the existence of multiple signaling pathways affected by the protein mutation causative of DYT1 dystonia, torsinA, paving the way for potentially multiple, novel targets for pharmacological intervention.

Plasticity, genetics and epigenetics in dystonia: An update.
Dystonia represents a group of movement disorders characterized by involuntary muscle contractions that result in abnormal posture and twisting movements. In the last 20 years several animal models have been generated, greatly improving our knowledge of the neural and molecular mechanism underlying this pathological condition, but the pathophysiology remains still poorly understood. In this review we will discuss recent genetic factors related to dystonia and the current understanding of synaptic plasticity alterations reported by both clinical and experimental research. We will also present recent evidence involving epigenetics mechanisms in dystonia.

Synaptic effects of ethanol on striatal circuitry: therapeutic implications for dystonia.
Alcohol consumption affects motor behavior and motor control. Both acute and chronic alcohol abuse have been extensively investigated; however, the therapeutic efficacy of alcohol on some movement disorders, such as myoclonus-dystonia or essential tremor, still does not have a plausible mechanistic explanation. Yet, there are surprisingly few systematic trials with

known GABAergic drugs mimicking the effect of alcohol on neurotransmission. In this brief survey, we aim to summarize the effects of EtOH on striatal function, providing an overview of its cellular and synaptic actions in a 'circuit-centered' view. In addition, we will review both experimental and clinical evidence, in the attempt to provide a plausible mechanistic explanation for alcohol-responsive movement disorders, with particular emphasis on dystonia. Different hypotheses emerge, which may provide a rationale for the utilization of drugs that mimic alcohol effects, predicting potential drug repositioning.

INTENSIVE SENSORIMOTOR REHABILITATION RESTORES GAIT DISFUNCTION AND MICROSTRUCTURE CAUSED BY EXPERIMENTAL CEREBRAL PALSY IN RATS

POSTER SESSION 07 - SECTION: NEURODEGENERATIVE DISEASES

Dini Ho[1], Eduardo Sanches[1], Audrey Toulotte[1], Yohan Van De Looij[1,2], Laetitia Baud[3], Quentin Barraud[3], Grégoire Courtine[3], Stéphane Sizonenko[1]
[1]University of Geneva, Division Of Child Development And Growth, Department Of Gynecology, Obstetrics And Pediatrics, Geneva, Switzerland, [2]Swiss Federal Institute of Technology (EPFL), Center For Biomedical Imaging (cibm), Lausanne, Switzerland, [3]Swiss Federal Institute of Technology (EPFL), 3 Center For Neuroprosthetics And Brain Mind Institute, Lausanne, Switzerland

Cerebral palsy (CP) is a major cause of locomotor and cognitive disabilities due to perinatal brain injury. Hand and Bimanual Intensive Therapy Including Lower Extremities (HABIT-ILE), a 2-week intensive rehabilitation protocol using sensorimotor training, has been shown to improve motor function and induce plastic changes in CP children. The study sought to model HABIT-ILE combining environmental enrichment and treadmill training (EETT) in a rodent model of CP evaluating early (P28) and late (P60) functional, biochemical and histological parameters. Pregnant Wistar rats were injected with LPS (200mg/kg i.p - E18/E19). At P0, pups were exposed to 20‘ anoxia at 37°C. From P2 to P21, hindlimbs were restricted for 16h/day. EETT lasted from P21 to P28. TT - 15 min/day at 7cm/s. EE - 7 days in enriched cages with sensorimotor stimulus. 3D kinematics was assessed at P21, P28, and P60. Ex-vivo MRI, histological analysis, and protein expression were assessed at P28 and P60. Principal Component analysis evidenced that EETT rescued gait abnormalities caused by CP animals at P28 and P60. At P28, EETT altered BDNF signaling and decreased cortical excitatory dysfunction induced by CP. Ex-vivo diffusion imaging showed early and late loss of brain microstructure loss in CP rats, not reversed by EETT at P28 but at P60 it restored basal ganglia and somatosensory cortex microstructure altered by CP. EETT restored myelination and decreased astrogliosis at P28. These evidences show that HABIT-ILE (EETT) induces early and long-term functional benefits modulating molecular and microstructural brain damage caused by CP.

DEVELOPMENTAL DEFECT OF THE CORTICO-STRIATAL CIRCUIT IN A MOUSE MODEL OF HUNTINGTON'S DISEASE

POSTER SESSION 07 - SECTION: NEURODEGENERATIVE DISEASES

Margaux Lebouc[1], Léa Bonamy[1], Maurice Garret[2], Jérôme Baufreton[1]
[1]CNRS UMR 5293, Institut Des Maladies Neurodégénératives, Bordeaux, France, [2]INCIA-UMR 5287, Cnrs/university Of Bordeaux, Bordeaux, France

Huntington's disease (HD) is usually defined as a neurodegenerative disorder affecting the striatum and the cortex at adult stages. However, recent studies suggest that this disease also implies early striatal developmental alterations. As this issue remains largely unexplored, the aim of this study is to identify when the first disease-related striatal impairments emerge. To answer this question, we are longitudinally studying the striatal development of the R6/1 mouse model of HD. This study is performed during the two first postnatal weeks as this period has been shown to be crucial for the maturation of MSN's morphological and electrophysiological properties. By using multiple immunohistochemical labeling techniques we are studying the distribution of medium spiny neurons (MSNs) in HD and WT mouse littermates. Using *ex vivo* whole-cell patch clamp electrophysiology we are also recording the intrinsic electrophysiological properties of MSNs as well as the establishment of the cortico-striatal glutamatergic transmission. Finally we are looking at the morphology of the recorded neurons, especially their dendritic complexity and their dendritic spines. Our results suggest that there is a biphasic alteration of D2-MSNs properties in R6/1 mice, highlighted by an early decreased excitability and higher dendritic complexity at postnatal days P0-3 that is then replaced by a hyperexcitability and a decreased dendritic complexity at P8-P9. These anatomical and electrophysiological data provide an insight into striatal developmental alterations in a mouse model of HD at very early stages.

DEEP BRAIN STIMULATION FOR THE TREATMENT OF TOURETTE'S SYNDROME: STRIATAL DISINHIBITION AS A RAT MODEL

POSTER SESSION 07 - SECTION: NEURODEGENERATIVE DISEASES

Boriss Sagalajev, Lina Lennartz, Niloofar Mokhtari, Veerle Visser-Vandewalle, Thibaut Sesia
University of Cologne, Faculty Of Medicine And University Hospital Cologne, Department Of Stereotactic And Functional Neurosurgery, Cologne, Germany

Tourette's syndrome (TS) represents a neurodevelopmental disorder characterized by the presence of motor and vocal tics. Typically, tics first appear in childhood and disappear in adolescence. Some patients, however, may continue to suffer from TS even after reaching adulthood and despite receiving psychological as well as pharmacological treatment. In the most severe cases, such patients often resort to neuromodulatory treatments such as deep brain stimulation (DBS). Recently, striatal disinhibition has been proposed as a rat model for the study of TS. However, whether this model responds to the same treatment as patients remains unknown. We, therefore, set out to determine whether it would respond to DBS.

Neurophysiological response properties of medullary pain-control neurons following chronic treatment with morphine or oxycodone: modulation by acute ketamine.
Descending facilitatory circuitry that involves the rostroventromedial medulla (RVM) exerts a significant role in the development of antinociceptive tolerance and hyperalgesia following chronic morphine treatment. The role of the RVM in the development of antinociceptive tolerance to oxycodone, another clinically used strong opioid, is not yet known. Ketamine, an -methyl-d-aspartate (NMDA) receptor antagonist, attenuates opioid antinociceptive tolerance, but its effect on RVM cell discharge in opioid-tolerant animals is not known. Here, we compared chronic effects of morphine and oxycodone on the discharge properties of RVM cells and attempted to attenuate chronic treatment-induced changes with ketamine. Parallel recordings of RVM cell discharge and limb withdrawal response were performed under light pentobarbital anesthesia in male rats following sustained systemic treatment with morphine or oxycodone at equianalgesic doses. Ongoing activity and the response to noxious heat and pinch were determined in pronociceptive RVM ON-cells and antinociceptive OFF-cells on the sixth treatment day. Proportions of RVM cell types were not changed. Chronic oxycodone induced antinociceptive tolerance both in limb withdrawal and RVM cell activity. Chronic morphine induced antinociceptive tolerance in limb withdrawal that was accompanied by pronociceptive heat response changes in RVM ON- and OFF-cells. A behaviorally subantinociceptive dose of acute ketamine reversed antinociceptive tolerance both to morphine and oxycodone in limb withdrawal and reversed the chronic morphine-induced pronociceptive discharge changes in RVM cells. The results indicate that an NMDA receptor-dependent descending pronociceptive circuitry involving the RVM has an important role in behavioral antinociceptive tolerance to morphine but not oxycodone. Morphine and oxycodone are two clinically used strong opioids. Chronic treatment with oxycodone as well as morphine can lead to analgesic tolerance and paradoxical hyperalgesia. Here we show that an -methyl-d-aspartate receptor-dependent pronociceptive change in discharge properties of rostroventromedial medullary neurons controlling spinal nociception has an important role in antinociceptive tolerance to morphine but not oxycodone. Interestingly, chronic oxycodone did not induce pronociceptive changes in the rostroventromedial medulla.

Amygdaloid administration of tetrapentylammonium attenuates development of pain and anxiety-like behavior following peripheral nerve injury.
The central amygdaloid nucleus (CeA) is involved in processing and descending regulation of pain. Amygdaloid mechanisms underlying pain processing and control are poorly known. Here we tested the hypothesis that perioperative CeA administration of tetrapentylammonium (TPA), a non-selective THIK-1 channel blocker and thereby inhibitor of microglia, attenuates development of chronic neuropathic pain and comorbid anxiety-like behavior.

Microglial pannexin-1 channel activation is a spinal determinant of joint pain.
Chronic joint pain such as mechanical allodynia is the most debilitating symptom of arthritis, yet effective therapies are lacking. We identify the pannexin-1 (Panx1) channel as a therapeutic target for alleviating mechanical allodynia, a cardinal sign of arthritis. In rats, joint pain caused by intra-articular injection of monosodium iodoacetate (MIA) was associated with spinal adenosine 5'-triphosphate (ATP) release and a microglia-specific up-regulation of P2X7 receptors (P2X7Rs). Blockade of P2X7R or ablation of spinal microglia prevented and reversed mechanical allodynia. P2X7Rs drive Panx1 channel activation, and in rats with mechanical allodynia, Panx1 function was increased in spinal microglia. Specifically, microglial Panx1-mediated release of the proinflammatory cytokine interleukin-1β (IL-1β) induced mechanical allodynia in the MIA-injected hindlimb. Intrathecal administration of the Panx1-blocking peptide panx suppressed the aberrant discharge of spinal laminae I-II neurons evoked by innocuous mechanical hindpaw stimulation in arthritic rats. Furthermore, mice with a microglia-specific genetic deletion of Panx1 were protected from developing mechanical allodynia. Treatment with probenecid, a clinically used broad-spectrum Panx1 blocker, resulted in a striking attenuation of MIA-induced mechanical allodynia and normalized responses in the dynamic weight-bearing test, without affecting acute nociception. Probenecid reversal of mechanical allodynia was also observed in rats 13 weeks after anterior cruciate ligament transection, a model of posttraumatic osteoarthritis. Thus, Panx1-targeted therapy is a new mechanistic approach for alleviating joint pain.

Oxidative Stress in the Amygdala Contributes to Neuropathic Pain.
Earlier studies indicate that the central nucleus of the amygdala (CeA) contributes to neuropathic pain. Here we studied whether amygdaloid administration of antioxidants or antagonists of TRPA1 that is among ion channels activated by oxidative stress attenuates nociceptive or affective pain in experimental neuropathy, and whether this effect involves amygdaloid astrocytes or descending serotonergic pathways acting on the spinal 5-HT receptor. The experiments were performed in rats with spared nerve injury (SNI). Drugs were administered through a chronic cannula in the CeA or internal capsule (control site), and an intrathecal catheter. Nociception was assessed using monofilaments and affective pain using conditioned place-aversion. Antioxidants or TRPA1 antagonists in the CeA attenuated both nociceptive and affective pain in SNI animals but not in sham controls or in a control injection site. Drugs influencing astroglia (a gap junction decoupler or a D-amino acid oxidase inhibitor) in the CeA had no effect on SNI rats, whereas local anesthesia of the CeA attenuated nociception. Spinally administered 5-HT receptor antagonist at a dose that had no effect alone prevented the antinociceptive effect of amygdaloid TRPA1 blockers. The results suggest that injury-induced amygdaloid oxidative stress that drives TRPA1 promotes neuropathic pain behavior. This pronociceptive effect involves suppression of medullospinal serotonergic feedback-inhibition acting on the spinal 5-HT receptor. While the CeA is involved in mediating the nerve injury-induced pronociception, it may not be a critical relay for the recruitment of medullospinal feedback-inhibition.

The medullary dorsal reticular nucleus as a relay for descending pronociception induced by the mGluR5 in the rat infralimbic cortex.
Metabotropic glutamate receptor 5 (mGluR5) activation in the infralimbic cortex (IL) induces pronociceptive behavior in healthy and monoarthritic rats. Here we studied whether the medullary dorsal reticular nucleus (DRt) and the spinal TRPV1 are mediating the IL/mGluR5-induced spinal pronociception and whether the facilitation of pain behavior is correlated with changes in spinal dorsal horn neuron activity. For drug administrations, all animals had a cannula in the IL as well as a cannula in the DRt or an intrathecal catheter. Heat-evoked paw withdrawal was used to assess pain behavior in awake animals. Spontaneous and heat-evoked discharge rates of single DRt neurons or spinal dorsal horn wide-dynamic range (WDR) and nociceptive-specific (NS) neurons were evaluated in lightly anesthetized animals. Activation of the IL/mGluR5 facilitated nociceptive behavior in both healthy and monoarthritic animals, and this effect was blocked by lidocaine or GABA receptor agonists in the DRt. IL/mGluR5 activation increased spontaneous and heat-evoked DRt discharge rates in healthy but not monoarthritic rats. In the spinal dorsal horn, IL/mGluR5 activation increased spontaneous activity of WDR neurons in healthy animals only, whereas heat-evoked responses of WDR and NS neurons were increased in both experimental groups. Intrathecally administered TRPV1 antagonist prevented the IL/mGluR5-induced pronociception in both healthy and monoarthritic rats. The results suggest that the DRt is involved in relaying the IL/mGluR5-induced spinal pronociception in healthy control but not monoarthritic animals. Spinally, the IL/mGluR5-induced behavioral heat hyperalgesia is mediated by TRPV1 and associated with facilitated heat-evoked responses of WDR and NS neurons.

Descending antinociception induced by secondary somatosensory cortex stimulation in experimental neuropathy: role of the

medullospinal serotonergic pathway.
Stimulation of the secondary somatosensory cortex (S2) has attenuated pain in humans and inflammatory nociception in animals. Here we studied S2 stimulation-induced antinociception and its underlying mechanisms in an experimental animal model of neuropathy induced by spinal nerve ligation (SNL). Effect of S2 stimulation on heat-evoked limb withdrawal latency was assessed in lightly anesthetized rats that were divided into three groups based on prior surgery and monofilament testing before induction of anesthesia:) sham-operated group and) hypersensitive and) nonhypersensitive (mechanically) SNL groups. In a group of hypersensitive SNL animals, a 5-HT receptor agonist was microinjected into the rostroventromedial medulla (RVM) to assess whether autoinhibition of serotonergic cell bodies blocks antinociception. Additionally, effect of S2 stimulation on pronociceptive ON-cells and antinociceptive OFF-cells in the RVM or nociceptive spinal wide dynamic range (WDR) neurons were assessed in anesthetized hypersensitive SNL animals. S2 stimulation induced antinociception in hypersensitive but not in nonhypersensitive SNL or sham-operated animals. Antinociception was prevented by a 5-HT receptor agonist in the RVM. Antinociception was associated with decreased duration of heat-evoked response in RVM ON-cells. In spinal WDR neurons, heat-evoked discharge was delayed by S2 stimulation, and this antinociceptive effect was prevented by blocking spinal 5-HT receptors. The results indicate that S2 stimulation suppresses nociception in SNL animals if SNL is associated with tactile allodynia-like hypersensitivity. In hypersensitive SNL animals, S2 stimulation induces antinociception mediated by medullospinal serotonergic pathways acting on the spinal 5-HT receptor, and partly through reduction of the RVM ON-cell discharge. Stimulation of S2 cortex, but not that of an adjacent cortical area, induced descending heat antinociception in rats with the spinal nerve ligation-induced model of neuropathy. Antinociception was bilateral, and it involved suppression of pronociceptive medullary cells and activation of serotonergic pathways that act on the spinal 5-HT receptor. S2 stimulation failed to induce descending antinociceptive effect in sham-operated controls or in nerve-ligated animals that had not developed mechanical hypersensitivity.

Regulation of neuropathic pain behavior by amygdaloid TRPC4/C5 channels.
Pain per se may increase anxiety and conversely, anxiety may increase pain. Therefore, a positive feedback loop between anxiety and pain possibly contributes to pain and suffering in some pathophysiological pain conditions, such as that induced by peripheral nerve injury. Recent results indicate that transient receptor channels 4 and 5 (TRPC4/C5) in the amygdala have anxiogenic effects in rodents, while their role in chronic pain conditions is not known. Here, we studied whether the amygdaloid TRPC4/C5 that are known to have anxiogenic properties contribute to the maintenance of sensory or affective aspects of pain in an experimental model of peripheral neuropathy. Rats with a spared nerve injury (SNI) model of neuropathy in the left hind limb had a chronic cannula for microinjections of drugs into the right amygdala or the internal capsule (a control site). Sensory pain was assessed by determining mechanical hypersensitivity with calibrated monofilaments and affective pain by determining aversive place-conditioning. Amygdaloid treatment with ML-204, a TRPC4/C5 antagonist, produced a dose-related (5-10 μg) antihypersensitivity effect, without obvious side-effects. Additionally, amygdaloid administration of ML-204 reduced affective-like pain behavior. In the internal capsule, ML-204 had no effect on hypersensitivity or affective-like pain in SNI animals. In healthy controls, amygdaloid administration of ML-204 failed to influence pain behavior induced by mechanical stimulation or noxious heat. The results indicate that the amygdaloid TRPC4/C5 contribute to maintenance of pain hypersensitivity and pain affect in neuropathy.
Neurosci Lett, 2015; 608
25557801: Sagalajev B, Bourbia N, Beloushko E, Wei H, Pertovaara A
Bidirectional amygdaloid control of neuropathic hypersensitivity mediated by descending serotonergic pathways acting on spinal 5-HT3 and 5-HT1A receptors.
Amygdala is involved in processing of primary emotions and particularly its central nucleus (CeA) also in pain control. Here we studied mechanisms mediating the descending control of mechanical hypersensitivity by the CeA in rats with a peripheral neuropathy in the left hind limb. For drug administrations, the animals had a guide cannula in the right CeA and an intrathecal catheter or another guide cannula in the medullary raphe. Hypersensitivity was tested with monofilaments. Glutamate administration in the CeA produced a bidirectional effect on hypersensitivity that varied from an increase at a low-dose (9μg) to a reduction at high doses (30-100μg). The increase but not the reduction of hypersensitivity was prevented by blocking the amygdaloid NMDA receptor with a dose of MK-801 that alone had no effects. The glutamate-induced increase in hypersensitivity was reversed by blocking the spinal 5-HT3 receptor with ondansetron, whereas the reduction in hypersensitivity was reversed by blocking the spinal 5-HT1A receptor with WAY-100635. Both the increase and decrease of hypersensitivity induced by amygdaloid glutamate treatment were reversed by medullary administration of a 5-HT1A agonist, 8-OH-DPAT, that presumably produced autoinhibition of serotonergic cell bodies in the medullary raphe. The results indicate that depending on the dose, glutamate in the CeA has a descending facilitatory or inhibitory effect on neuropathic pain hypersensitivity. Serotoninergic raphe neurons are involved in mediating both of these effects. Spinally, the 5-HT3 receptor

contributes to the increase and the 5-HT1A receptor to the decrease of neuropathic hypersensitivity induced by amygdaloid glutamate.

24747685: Bourbia N, Sagalajev B, Pertovaara A
Descending effect on spinal nociception by amygdaloid glutamate varies with the submodality of noxious test stimulation. Amygdala has an important role in the processing of primary emotions, such as fear. Additionally, amygdala is involved in processing and modulation of pain. While the amygdala, particularly its central nucleus (CeA), has been shown to contribute to pain control, the descending pain regulation by the CeA is still only partly characterized. Here heat and mechanical nociception was tested in both hind limbs of healthy rats with a chronic guide cannula for microinjection of glutamate into the CeA of the left or right hemisphere. The aim was to assess whether the descending pain regulatory effect by glutamate in the amygdala varies with the submodality or the body side of nociceptive testing, brain hemisphere or the amygdaloid glutamate receptor. Motor performance was assessed with the Rotarod test. Amygdaloid glutamate, independent of the treated hemisphere, produced a dose-related heat and mechanical antinociception that varied with the submodality of testing. Heat antinociception was short lasting (minutes), bilateral and not reversed by blocking the amygdaloid NMDA receptor with MK-801. In contrast, mechanical antinociception lasted longer (>20 min), was predominantly contralateral and reversed by blocking the amygdaloid NMDA receptor. At an antinociceptive dose, amygdaloid glutamate failed to influence motor performance. The results indicate that independent of the brain hemisphere, the spatial extent and duration of the descending antinociceptive effect induced by amygdaloid glutamate varies with the amygdaloid glutamate receptor and the submodality of pain.

IDENTIFICATION AND FUNCTIONAL ANALYSIS OF PKCγ MOLECULAR TARGETS DURING PURKINJE CELL DEVELOPMENT

POSTER SESSION 07 - SECTION: NEURODEGENERATIVE DISEASES

Paula Torrents Solé, Josef Kapfhammer, Etsuko Shimobayashi
Anatomical Institute, Department Of Biomedicine, University Of Basel, Basel, France

Spinocerebellar ataxia 14 (SCA14) is a rare autosomal dominant neurodegenerative disease caused by mutations in protein kinase C gamma gene (PRKCG, PKCγ protein) leading to motor deficits and cognitive decline. PKCγ is a signalling protein strongly expressed in Purkinje cells (PCs) known to be involved in the regulation of synapse formation and PC dendritic development. The effects of PKCγ are mediated by phosphorylation of target proteins and for dendritic development the regulation of cytoskeletal function and dynamics will play a critical role. However, the interaction of PKCγ with cytoskeletal regulators is still not very well understood. In this project, we are taking advantage of PKCγ mutant mouse lines expressing a constitutively active PKCγ and causing a SCA14-like phenotype. Using proteomic and phospho-proteomic analyses we compared the expression and phosphorylation of potential target proteins in normal mice with those of mice having Purkinje cells with a constitutively active PKCγ. This analysis yielded several candidate genes showing an altered expression and/or phosphorylation in the presence of constitutively active PKCγ. The function and the involvement of these genes in PKCγ signalling will be explored by studying the cerebellar expression and phosphorylation of these genes in more detail and by the manipulation of gene and phosphorylation in organotypic slice cultures and dissociated cerebellar cultures in vitro followed by morphological analysis of PC dendritic arbours. The results of the current analysis will be presented at the meeting and will provide new insights into PKCγ molecular targets during PC development.

Aims The zebrafish (*Danio rerio*) is an important model for the study of hereditary neurological disorders, which shares 70 % of homology with human genome and a similar organization of the central nervous system (CNS). Our objective is to study how the NPC1 gene is involved in Niemann Pick disease type C (NPC), a neurodegenerative lysosomal disorder. NPC is a sphingolipidosis, transmitted by autosomal recessive inheritance and characterized by an accumulation of lipids in different organs. Clinical symptoms start at childhood and the most usual manifestations include hepatosplenomegaly and ataxia. Currently there is no effective treatment for this disease. **Methods** By using CRISPR/Cas9 system, we developed a zebrafish *npc1* mutant line, in which we carried out a comprehensive phenotypic and histological characterization, as well as immunotyping, behavioural analysis and RNAseq assay. **Results** We observed high lethality, all larvae died before reaching the adult stage. *Npc1* mutant larvae were smaller than wild type, their motor function was reduced and they were presented with filipin aggregations and liver and spleen damage. In addition, RNAseq analysis showed more than 249 genes differentially expressed between *npc1* mutants and control, such as *npc1* and genes related development of the CNS and lipid exchange and metabolism **Conclusions** *Npc1* zebrafish model showed similar symptoms to NPC human patients. The use of zebrafish models for NPC will improve our knowledge on the underlying mechanisms which cause this disease, an essential step for the development of new therapeutic strategies.

Zebrafish Models of Autosomal Recessive Ataxias.
Autosomal recessive ataxias are much less well studied than autosomal dominant ataxias and there are no clearly defined systems to classify them. Autosomal recessive ataxias, which are characterized by neuronal and multisystemic features, have significant overlapping symptoms with other complex multisystemic recessive disorders. The generation of animal models of neurodegenerative disorders increases our knowledge of their cellular and molecular mechanisms and helps in the search for new therapies. Among animal models, the zebrafish, which shares 70% of its genome with humans, offer the advantages of being small in size and demonstrating rapid development, making them optimal for high throughput drug and genetic screening. Furthermore, embryo and larval transparency allows to visualize cellular processes and central nervous system development in vivo. In this review, we discuss the contributions of zebrafish models to the study of autosomal recessive ataxias characteristic phenotypes, behavior, and gene function, in addition to commenting on possible treatments found in these models. Most of the zebrafish models generated to date recapitulate the main features of recessive ataxias.

Zebrafish Models of Autosomal Dominant Ataxias.
Hereditary dominant ataxias are a heterogeneous group of neurodegenerative conditions causing cerebellar dysfunction and characterized by progressive motor incoordination. Despite many efforts put into the study of these diseases, there are no effective treatments yet. Zebrafish models are widely used to characterize neuronal disorders due to its conserved vertebrate genetics that easily support genetic edition and their optic transparency that allows observing the intact CNS and its connections. In addition, its small size and external fertilization help to develop high throughput assays of candidate drugs. Here, we discuss the contributions of zebrafish models to the study of dominant ataxias defining phenotypes, genetic function, behavior and possible treatments. In addition, we review the zebrafish models created for X-linked repeat expansion diseases X-fragile/fragile-X tremor ataxia. Most of the models reviewed here presented neuronal damage and locomotor

deficits. However, there is a generalized lack of zebrafish adult heterozygous models and there are no knock-in zebrafish models available for these diseases. The models created for dominant ataxias helped to elucidate gene function and mechanisms that cause neuronal damage. In the future, the application of new genetic edition techniques would help to develop more accurate zebrafish models of dominant ataxias.

Decline in Constitutive Proliferative Activity in the Zebrafish Retina with Ageing.
It is largely assumed that the teleost retina shows continuous and active proliferative and neurogenic activity throughout life. However, when delving into the teleost literature, one finds that assumptions about a highly active and continuous proliferation in the adult retina are based on studies in which proliferation was not quantified in a comparative way at the different life stages or was mainly studied in juveniles/young adults. Here, we performed a systematic and comparative study of the constitutive proliferative activity of the retina from early developing (2 days post-fertilisation) to aged (up to 3-4 years post-fertilisation) zebrafish. The mitotic activity and cell cycle progression were analysed by using immunofluorescence against pH3 and PCNA, respectively. We observed a decline in the cell proliferation in the retina with ageing despite the occurrence of a wave of secondary proliferation during sexual maturation. During this wave of secondary proliferation, the distribution of proliferating and mitotic cells changes from the inner to the outer nuclear layer in the central retina. Importantly, in aged zebrafish, there is a virtual disappearance of mitotic activity. Our results showing a decline in the proliferative activity of the zebrafish retina with ageing are of crucial importance since it is generally assumed that the fish retina has continuous proliferative activity throughout life.

Cell senescence contributes to tissue regeneration in zebrafish.
Cellular senescence is a stress response that limits the proliferation of damaged cells by establishing a permanent cell cycle arrest. Different stimuli can trigger senescence but excessive production or impaired clearance of these cells can lead to their accumulation during aging with deleterious effects. Despite this potential negative side of cell senescence, its physiological role as a pro-regenerative and morphogenetic force has emerged recently after the identification of programmed cell senescence during embryogenesis and during wound healing and limb regeneration. Here, we explored the conservation of tissue injury-induced senescence in a model of complex regeneration, the zebrafish. Fin amputation in adult fish led to the appearance of senescent cells at the site of damage, and their removal impaired tissue regeneration. Despite many conceptual similarities, this tissue repair response is different from developmental senescence. Our results lend support to the notion that cell senescence is a positive response promoting tissue repair and homeostasis.

Developmentally-programmed cellular senescence is conserved and widespread in zebrafish.
Cellular senescence is considered a stress response imposing a stable cell cycle arrest to restrict the growth of damaged cells. More recently however, cellular senescence was identified during mouse embryo development at particular structures during specific periods of time. This programmed cell senescence has been proposed to serve developmental and morphogenetic functions and to potentially represent an evolutionary origin of senescence. Cellular senescence has also been described to take place during bird (chick and quail) and amphibian (xenopus and axoltl) development. Fish however, have been described to show a very narrow and restricted pattern of developmental cell senescence. Here we carried out a detailed characterization of senescence during zebrafish development and found it to be conserved and widespread. Apart from yolk and cloaca, previously described structures, we also identified senescence in the developing central nervous system, intestine, liver, pronephric ducts, and crystalline. Interestingly, senescence at these developing structures disappeared upon treatment with senolytic compound ABT-263, supporting their senescent identity and opening the possibility of studying the contribution of this process to development. In summary, our findings extend the description of developmentally-programmed cell senescence to lower vertebrates contributing to the notion of the relevance of this process for embryo development.

Neural connections of the pretectum in zebrafish (Danio rerio).
The pretectum is a complex region of the caudal diencephalon which in adult zebrafish comprises both retinorecipient (parvocellular superficial, central, intercalated, paracommissural, and periventricular) and non-retinorecipient (magnocellular superficial, posterior, and accessory) pretectal nuclei distributed from periventricular to superficial regions. We conducted a comprehensive study of the connections of pretectal nuclei by using neuronal tracing with fluorescent carbocyanine dyes. This study reveals specialization of efferent connections of the various pretectal nuclei, with nuclei projecting to the optic

tectum (paracommissural, central, and periventricular pretectal nuclei), the torus longitudinalis and the cerebellar corpus (paracommissural, central, and intercalated pretectal nuclei), the lateral hypothalamus (magnocellular superficial, posterior, and central pretectal nuclei), and the tegmental regions (accessory and superficial pretectal nuclei). With regard to major central afferents to the pretectum, we observed projections from the telencephalon to the paracommissural and central pretectal nuclei, from the optic tectum to the paracommissural, central, accessory and parvocellular superficial pretectal nuclei, from the cerebellum to the paracommissural and periventricular pretectal nuclei and from the nucleus isthmi to the parvocellular superficial and accessory pretectal nuclei. The parvocellular superficial pretectal nucleus sends conspicuous projections to the contralateral magnocellular superficial pretectal nucleus. The composite figure of results reveals large differences in connections of neighbor pretectal nuclei, indicating high degree of nuclear specialization. Our results will have important bearings in functional studies that analyze the relationship between specific circuits and behaviors in zebrafish. Comparison with results available in other species also reveals differences in the organization and connections of the pretectum in vertebrates.

Background: Spinocerebellar ataxia type 3 (SCA3) is a neurodegenerative disease, depicting a very heterogenous clinical presentation, comprising mainly motor deficits. Previous clinical and functional studies have related cerebellar dysfunction with cognitive and mood-related disturbances – the so called, cerebellar cognitive affective syndrome (CCAS). SCA3 patients report depressive and anxiety symptoms, often attributed to the negative prospects of disease, but which can, alternatively, be inherent to the disease state, as part of the CCAS. **Aims**: SCA3 patients are more prone to suffer from stress; here and using the CMVMJD135 mouse model we aim to: (i) explore the presence of a CCAS-live presentation, (ii) evaluate the HPA-axis mediated stress response after acute stress, and (iii) study the impact of a chronic stress exposure in the motor function in these mice. **Methods:** Longitudinal evaluations were performed from 6 to 36 weeks of age. Different behavioral tests were applied to assess mood, anxiety, and cognition throughout disease progression. To evaluate HPA-axis modulation in SCA3, corticosterone levels were measured at several timepoints of disease progression at basal conditions and after acute stress. **Results:** SCA3 mice do not exhibit anhedonia, anxiety, lack of coping behavior or cognitive deficits in the measured paradigms. No major impact was observed on disease progression upon exposure to a 6-week chronic unpredictable stress protocol. **Conclusions:** Although no alterations were observed SCA3 mice behavior, as they lack awareness of their disease state, by exploring these comorbidities in animal models we contribute to a better understanding of the disease process in SCA3 patients.

Beyond New Neurons in the Adult Hippocampus: Imipramine Acts as a Pro-Astrogliogenic Factor and Rescues Cognitive Impairments Induced by Stress Exposure.
Depression is a prevalent, socially burdensome disease. Different studies have demonstrated the important role of astrocytes in the pathophysiology of depression as modulators of neurotransmission and neurovascular coupling. This is evidenced by astrocyte impairments observed in brains of depressed patients and the appearance of depressive-like behaviors upon astrocytic dysfunctions in animal models. However, little is known about the importance of de novo generated astrocytes in the mammalian brain and in particular its possible involvement in the precipitation of depression and in the therapeutic actions of current antidepressants (ADs). Therefore, we studied the modulation of astrocytes and adult astrogliogenesis in the hippocampal dentate gyrus (DG) of rats exposed to an unpredictable chronic mild stress (uCMS) protocol, untreated and treated for two weeks with antidepressants-fluoxetine and imipramine. Our results show that adult astrogliogenesis in the DG is modulated by stress and imipramine. This study reveals that distinct classes of ADs impact differently in the astrogliogenic process, showing different cellular mechanisms relevant to the recovery from behavioral deficits induced by chronic stress exposure. As such, in addition to those resident, the newborn astrocytes in the hippocampal DG might also be promising therapeutic targets for future therapies in the neuropsychiatric field.

Suppression of adult cytogenesis in the rat brain leads to sex-differentiated disruption of the HPA axis activity.
The action of stress hormones, mainly glucocorticoids, starts and coordinates the systemic response to stressful events. The HPA axis activity is predicated on information processing and modulation by upstream centres, such as the hippocampus where adult-born neurons (hABN) have been reported to be an important component in the processing and integration of new information. Still, it remains unclear whether and how hABN regulates HPA axis activity and CORT production, particularly

when considering sex differences.

Preclinical Assessment of Mesenchymal-Stem-Cell-Based Therapies in Spinocerebellar Ataxia Type 3.
The low regeneration potential of the central nervous system (CNS) represents a challenge for the development of new therapeutic strategies for neurodegenerative diseases, including spinocerebellar ataxias. Spinocerebellar ataxia type 3 (SCA3)-or Machado-Joseph disease (MJD)-is the most common dominant ataxia, being mainly characterized by motor deficits; however, SCA3/MJD has a complex and heterogeneous pathophysiology, involving many CNS brain regions, contributing to the lack of effective therapies. Mesenchymal stem cells (MSCs) have been proposed as a potential therapeutic tool for CNS disorders. Beyond their differentiation potential, MSCs secrete a broad range of neuroregulatory factors that can promote relevant neuroprotective and immunomodulatory actions in different pathophysiological contexts. The objective of this work was to study the effects of (1) human MSC transplantation and (2) human MSC secretome (CM) administration on disease progression in vivo, using the CMVMJD135 mouse model of SCA3/MJD. Our results showed that a single CM administration was more beneficial than MSC transplantation-particularly in the cerebellum and basal ganglia-while no motor improvement was observed when these cell-based therapeutic approaches were applied in the spinal cord. However, the effects observed were mild and transient, suggesting that continuous or repeated administration would be needed, which should be further tested.

Cell Cycle Regulation of Hippocampal Progenitor Cells in Experimental Models of Depression and after Treatment with Fluoxetine.
Changes in adult hippocampal cell proliferation and genesis have been largely implicated in depression and antidepressant action, though surprisingly, the underlying cell cycle mechanisms are largely undisclosed. Using both an unpredictable chronic mild stress (uCMS) rat model of depression and rat hippocampal-derived neurosphere culture approaches, we aimed to unravel the cell cycle mechanisms regulating hippocampal cell proliferation and genesis in depression and after antidepressant treatment. We show that the hippocampal dentate gyrus (hDG) of uCMS animals have less proliferating cells and a decreased proportion of cells in the G2/M phase, suggesting a G1 phase arrest; this is accompanied by decreased levels of cyclin D1, E, and A expression. Chronic fluoxetine treatment reversed the G1 phase arrest and promoted an up-regulation of cyclin E. , dexamethasone (DEX) decreased cell proliferation, whereas the administration of serotonin (5-HT) reversed it. DEX also induced a G1-phase arrest and decreased cyclin D1 and D2 expression levels while increasing p27. Additionally, 5-HT treatment could partly reverse the G1-phase arrest and restored cyclin D1 expression. We suggest that the anti-proliferative actions of chronic stress in the hDG result from a glucocorticoid-mediated G1-phase arrest in the progenitor cells that is partly mediated by decreased cyclin D1 expression which may be overcome by antidepressant treatment.

Astrocytic signaling supports hippocampal-prefrontal theta synchronization and cognitive function.
Astrocytes interact with neurons at the cellular level through modulation of synaptic formation, maturation, and function, but the impact of such interaction into behavior remains unclear. Here, we studied the dominant negative SNARE (dnSNARE) mouse model to dissect the role of astrocyte-derived signaling in corticolimbic circuits, with implications for cognitive processing. We found that the blockade of gliotransmitter release in astrocytes triggers a critical desynchronization of neural theta oscillations between dorsal hippocampus and prefrontal cortex. Moreover, we found a strong cognitive impairment in tasks depending on this network. Importantly, the supplementation with d-serine completely restores hippocampal-prefrontal theta synchronization and rescues the spatial memory and long-term memory of dnSNARE mice. We provide here novel evidence of long distance network modulation by astrocytes, with direct implications to cognitive function.

Hippocampal cytogenesis abrogation impairs inter-regional communication between the hippocampus and prefrontal cortex and promotes the time-dependent manifestation of emotional and cognitive deficits.
Impaired ability to generate new cells in the adult brain has been linked to deficits in multiple emotional and cognitive behavioral domains. However, the mechanisms by which abrogation of adult neural stem cells (NSCs) impacts on brain function remains controversial. We used a transgenic rat line, the GFAP-Tk, to selectively eliminate NSCs and assess

repercussions on different behavioral domains. To assess the functional importance of newborn cells in specific developmental stages, two parallel experimental timeframes were adopted: a short- and a long-term timeline, 1 and 4 weeks after the abrogation protocol, respectively. We conducted in vivo electrophysiology to assess the effects of cytogenesis abrogation on the functional properties of the hippocampus and prefrontal cortex, and on their intercommunication. Adult brain cytogenesis abrogation promoted a time-specific installation of behavioral deficits. While the lack of newborn immature hippocampal neuronal and glial cells elicited a behavioral phenotype restricted to hyperanxiety and cognitive rigidity, specific abrogation of mature new neuronal and glial cells promoted the long-term manifestation of a more complex behavioral profile encompassing alterations in anxiety and hedonic behaviors, along with deficits in multiple cognitive modalities. More so, abrogation of 4 to 7-week-old cells resulted in impaired electrophysiological synchrony of neural theta oscillations between the dorsal hippocampus and the medial prefrontal cortex, which are likely to contribute to the described long-term cognitive alterations. Hence, this work provides insight on how newborn neurons and astrocytes display different functional roles throughout different maturation stages, and establishes common ground to reconcile contrasting results that have marked this field.

Differential and converging molecular mechanisms of antidepressants' action in the hippocampal dentate gyrus.
Major depression is a highly prevalent, multidimensional disorder. Although several classes of antidepressants (ADs) are currently available, treatment efficacy is limited, and relapse rates are high; thus, there is a need to find better therapeutic strategies. Neuroplastic changes in brain regions such as the hippocampal dentate gyrus (DG) accompany depression and its amelioration with ADs. In this study, the unpredictable chronic mild stress (uCMS) rat model of depression was used to determine the molecular mediators of chronic stress and the targets of four ADs with different pharmacological profiles (fluoxetine, imipramine, tianeptine, and agomelatine) in the hippocampal DG. All ADs, except agomelatine, reversed the depression-like behavior and neuroplastic changes produced by uCMS. Chronic stress induced significant molecular changes that were generally reversed by fluoxetine, imipramine, and tianeptine. Fluoxetine primarily acted on neurons to reduce the expression of pro-inflammatory response genes and increased a set of genes involved in cell metabolism. Similarities were found between the molecular actions and targets of imipramine and tianeptine that activated pathways related to cellular protection. Agomelatine presented a unique profile, with pronounced effects on genes related to Rho-GTPase-related pathways in oligodendrocytes and neurons. These differential molecular signatures of ADs studied contribute to our understanding of the processes implicated in the onset and treatment of depression-like symptoms.

The modulation of adult neuroplasticity is involved in the mood-improving actions of atypical antipsychotics in an animal model of depression.
Depression is a prevalent psychiatric disorder with an increasing impact in global public health. However, a large proportion of patients treated with currently available antidepressant drugs fail to achieve remission. Recently, antipsychotic drugs have received approval for the treatment of antidepressant-resistant forms of major depression. The modulation of adult neuroplasticity, namely hippocampal neurogenesis and neuronal remodeling, has been considered to have a key role in the therapeutic effects of antidepressants. However, the impact of antipsychotic drugs on these neuroplastic mechanisms remains largely unexplored. In this study, an unpredictable chronic mild stress protocol was used to induce a depressive-like phenotype in rats. In the last 3 weeks of stress exposure, animals were treated with two different antipsychotics: haloperidol (a classical antipsychotic) and clozapine (an atypical antipsychotic). We demonstrated that clozapine improved both measures of depressive-like behavior (behavior despair and anhedonia), whereas haloperidol aggravated learned helplessness in the forced-swimming test and behavior flexibility in a cognitive task. Importantly, an upregulation of adult neurogenesis and neuronal survival was observed in animals treated with clozapine, whereas haloperidol promoted a downregulation of these processes. Furthermore, clozapine was able to re-establish the stress-induced impairments in neuronal structure and gene expression in the hippocampus and prefrontal cortex. These results demonstrate the modulation of adult neuroplasticity by antipsychotics in an animal model of depression, revealing that the atypical antipsychotic drug clozapine reverts the behavioral effects of chronic stress by improving adult neurogenesis, cell survival and neuronal reorganization.

Adult hippocampal neuroplasticity triggers susceptibility to recurrent depression.

Depression is a highly prevalent and recurrent neuropsychiatric disorder associated with alterations in emotional and cognitive domains. Neuroplastic phenomena are increasingly considered central to the etiopathogenesis of and recovery from depression. Nevertheless, a high number of remitted patients experience recurrent episodes of depression, remaining unclear how previous episodes impact on behavior and neuroplasticity and/or whether modulation of neuroplasticity is important to prevent recurrent depression. Through re-exposure to an unpredictable chronic mild stress protocol in rats, we observed the re-appearance of emotional and cognitive deficits. Furthermore, treatment with the antidepressants fluoxetine and imipramine was effective to promote sustained reversion of a depressive-like phenotype; however, their differential impact on adult hippocampal neuroplasticity triggered a distinct response to stress re-exposure: while imipramine re-established hippocampal neurogenesis and neuronal dendritic arborization contributing to resilience to recurrent depressive-like behavior, stress re-exposure in fluoxetine-treated animals resulted in an overproduction of adult-born neurons along with neuronal atrophy of granule neurons, accounting for an increased susceptibility to recurrent behavioral changes typical of depression. Strikingly, cell proliferation arrest compromised the behavior resilience induced by imipramine and buffered the susceptibility to recurrent behavioral changes promoted by fluoxetine. This study shows that previous exposure to a depressive-like episode impacts on the behavioral and neuroanatomical changes triggered by subsequent re-exposure to similar experimental conditions and reveals that the proper control of adult hippocampal neuroplasticity triggered by antidepressants is essential to counteract recurrent depressive-like episodes.

Astrocytic plasticity at the dorsal dentate gyrus on an animal model of recurrent depression.
Astrocytes are now known to play crucial roles in the central nervous system, supporting and closely interacting with neurons and therefore able to modulate brain function. Both human postmortem studies in brain samples from patients diagnosed with Major Depressive Disorder and from animal models of depression reported numerical and morphological astrocytic changes specifically in the hippocampus. In particular, these studies revealed significant reductions in glial cell density denoted by a decreased number of S100B-positive cells and a decrease in GFAP expression in several brain regions including the hippocampus. To reveal plastic astrocytic changes in the context of recurrent depression, we longitudinally assessed dynamic astrocytic alterations (gene expression, cell densities and morphologic variations) in the hippocampal dentate gyrus under repeated exposure to unpredictable chronic mild stress (uCMS) and upon treatment with two antidepressants, fluoxetine and imipramine. Both antidepressants decreased astrocytic complexity immediately after stress exposure. Moreover, we show that astrocytic alterations, particularly an increased number of S100B-positive cells, are observed after recurrent stress exposure. Interestingly, these alterations were prevented at the long-term by either fluoxetine or imipramine treatment.
